Dr. GEORGE D. MCGAURAN, City Physician of Newburyport, died on June 15, at the age of seventy-one years. He was graduated from the Eclectic Medical College, New York, in 1875 and was a consultant on the staff of the Anne Jacques Hospital.

Dr. WILLIAM CALHOUN EBAUGH, formerly of Salt Lake City, died at the home of a relative in Granville, Ohio, on June 10, at the age of eighty-two years.

Dr. JACOB PRESTON SARGENT of Lodi, Cal., a graduate of Bellevue Hospital Medical College in 1886, died in a San Francisco hospital on June 7, at the age of fifty-eight years.

Dr. LEONARD BRIGGS OLIVER of Chula Vista, Cal., a graduate of the State University of Iowa College of Medicine in 1887, died suddenly on June 10, at the age of sixty-three years. He formerly practised medicine in Chicago.

Dr. EDWIN A. WEIMER of Peoria, a graduate of Rush Medical College in 1895, died in a hospital in Elkhart, Ind., as a result of injuries received in an automobile accident, on June 7, at the age of fifty years.

Dr. ALBERT WENTWORTH POWERS of Fountain, Minn., a graduate of Rush Medical College in 1872, died on May 29, at the age of seventy-one years.

Dr. HENRY J. LACIAR of Bethlehem, Pa., a graduate of the College of Physicians and Surgeons, Baltimore, in 1881, died following a stroke of apoplexy on June 13, at the age of sixty-five years.

Dr. A. J. GOURLEY, a graduate of the Kentucky School of Medicine, Louisville, Ky., in 1890, died recently at his home in Lick Creek, Ill., at the age of sixty-nine years.

Dr. FRANK B. SEWALL of Marlin, Texas, died on June 6, at the age of forty years. He was graduated from the University of Virginia Department of Medicine in 1902, and served as first lieutenant in the Medical Corps of the A. E. F. in France during the World War.

Dr. MOULTON J. KLINE of Orefield, Pa., a graduate of the University of Pennsylvania in 1875, and at one time a member of the Pennsylvania State Legislature, died from uremia at Central Valley, on May 15, at the age of sixty-six years.

Dr. JOHNSON MCKEE SITES, a graduate of New York University in 1885, and a former president of the Eastern Panhandle Medical Society, died at his home in Martinsburg, W. Va., on May 23, at the age of fifty-nine years. He was a member and president of the State board of examiners of nurses.

Dr. FREDERICK A. TUCKER of Noblesville, Ind., a graduate of Rush Medical College in 1898, died on June 7, following an operation for appendicitis, at the age of forty-eight years. He was a Lieutenant-Colonel in the United States Army during the World War, in charge of Base Hospital No. 1, near Paris, for eighteen months.

Dr. A. B. CAMPBELL of Orrville, Ohio, a graduate of the University of Michigan in 1871, died on June 2, at the age of seventy-six years.

Dr. WILBUR S. WATSON of Danbury, Conn., formerly surgeon general and medical director of the Connecticut National Guard, died on June 7, at the age of sixty-nine years. He was graduated from the Long Island College Hospital in 1886. He was a member of the medical staff of the Danbury Hospital and a former member of the board of aldermen of Danbury.

Correspondence.

NOW IT CAN BE TOLD.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Sir Philip Gibbs a year or so ago toured this country lecturing upon his experiences in the great war. The title of his lecture was "Now It Can Be Told." It seems to me that the same title can be used for what I am about to say.

Dr. J. Milton Mabbott in a letter published in your journal, July 30, 1921, makes certain statements concerning me, some of which do not interest me because they are merely expressions of his personal attitude toward me. The part of his letter that really interests me is his statement that I am "largely responsible for the chaotic conditions now existing in New York State, and New York City in particular."

It may be well, therefore, to recapitulate some of the history of narcotic legislation of recent years to show that this statement is false. The endorsement by the State Society of the Cotillo Bill of last year with which the Smith-Fearon Bill of this year is in large part identical, was secured by a snap vote in the House of Delegates on the last day of the session in 1920, when less than half of the House were present and without any discussion of the proposed bill whatsoever. This action related only to the bill of that year with which I had no concern because at that time I was not an officer of the State Society. So far as securing an endorsement for any bill either on the floor of the House of Delegates or in the Council this year the facts are these: Both of these bills were referred to a reference committee of the House of Delegates composed of Dr. Charles D. Stockton of Buffalo, chairman, Dr. T. J. Farrell of Utica, and others, who, after hearing the arguments upon these measures, referred the whole question to the House of Delegates. Even Dr. Mabbott may recall that it was I who made the motion to refer these bills to the Council for action, and I am quite sure that any other member of the Council will recall that at the meeting of this body held immediately after the adjournment of the State Society, I suggested that the first Smith Bill abolishing the Narcotic Control Commission be recommended to the Governor for signature and that he be requested to veto all of the other bills. In this matter the only law concerning the use of narcotic drugs which would be operative, would be Federal. Dr. E. Eliot Harris, I am quite sure, can verify this statement. So that it can be seen that so far as my position was con-

cerned as an officer of the Society I advocated no legislation from any personal or prejudiced viewpoint but endeavored to keep an eye clear for the best interests of the public and the medical profession. The Governor followed out to the letter the request of the Council.

What precipitated this whole conflict? The Narcotic Control Commission which was appointed in conformity with the statute passed as suggested by the Whitney Commission, antagonized the profession and the public by its promulgated rules and regulations. It made itself a nuisance and a thorn in the flesh to the ordinary practising physician and surgeon who was not in any way treating addicts; for this reason the profession revolted against this dictatorial administration of the law. The Commissioner of Narcotic Drug Control, a most estimable gentleman and a personal friend of mine from boyhood, told me after the bill was introduced to abolish his Commission that he could not understand why this attitude of antagonism was assumed by the medical profession, when, as he stated, he, knowing that this was so largely a medical question and that he was not well enough informed, had been advised by such eminent men as Dr. Alexander Lambert, Dr. E. Eliot Harris, Dr. Alfred C. Prentice, Dr. S. Dana Hubbard, and others. He further stated that he was endeavoring to enforce the State law on the same lines as those which the Smith-Fearon bill would make statutory. Dr. Prentice has stated that the Smith-Fearon Bill was formulated solely for the purpose of enacting a State statute, which would bring the State law in conformity, not with the Federal law, but with the interpretation of that law as formulated by its administrators through rules and regulations. It may be seen then, that the group of men who, Commissioner Herrick states, acted as his advisors and some of whom were the proponents of the Smith-Fearon Bill, were to a large degree one and the same, and that the sole purpose in proposing the Smith-Fearon Bill of this year and the Cotillo Bill of last year was to put into statute law what until then existed solely in the way of rules and regulations as promulgated by the Commission on Narcotic Drug Control.

It would seem then that it is not I who am responsible for the "chaotic conditions," etc., but rather the group of men who by their advice of Commissioner Herrick secured the antagonism of the medical profession. No one in the medical profession in the State is less satisfied than I with the present rotten conditions in relation to the study and treatment of narcotic drug addiction and the necessary police power for the management of criminal illicit purveyors of narcotic drugs. I can conceive of no more inhumane and horrible lack of humanitarian interest in the care of the sick, whether they be criminal or non-criminal, than is evidenced by the recent newspaper accounts—if they be true—and they must be true because of the unvarying character of them in all of the journals of the City of New York—which is the result of the adoption of an amendment to the sanitary code of New York City in line with the provisions of the Smith-Fearon Bill. Whether or not the addict is sick, as I believe; whether as a result of his own volition or not; whether he is a criminal or non-criminal; the same brutal treatment would not be meted out to him if instead of being addicted to narcotic drugs he had, let us say, typhoid, venereal disease—the result of his own act—diphtheria, or any of the other infectious diseases, even leprosy.

As an evidence of my position upon this matter may I further say that in my report submitted officially to the House of Delegates of the State Society, I made no recommendation as to the enactment of any narcotic legislation, but I did recommend—and this recommendation was adopted by the House of Delegates—as follows:

"That a committee be appointed by the House of Delegates for the purpose of prosecuting a real State-wide investigation—not the closed chamber, five-hour, stereotyped, dictated sort—on the subject of narcotic addiction disease, and that their report embody suggested changes in the present law, both Federal and State, that they deem necessary for (*a*) proper medical care, and (*b*) police regulation. Furthermore that this committee meet with such other bodies, magisterial, charitable, health, and educational in the hope that this most important question may be clarified and, if possible, an unanimity of opinion arrived at which will have imperative effect upon legislatures both national and State."

This is my position: that none of the bills thus far suggested meets the situation adequately, not even the Federal law, which is bastard legislation enacted by subterfuge as a revenue law and administered as a police law. The medical profession has been remiss in its duty in this matter as it was remiss in its duty for one hundred years on the question of venereal diseases. Every one has been afraid to touch it because of fear of being dirtied by it. It is time that this attitude were changed and I for one will do all that properly lies within my power to change it. I need no defenders and I wish none. I shall not be swayed from my purpose by the methods that have been used against me during the past seven years by those who opposed me on Compulsory Health Insurance and State Medicine as well as those who now take sides against me on the subject of Narcotic Addiction. From now on the best means of cleaning the Augean stables of this accumulated mess should be by use of the truth, the whole truth, and nothing but the truth. I hold no brief from any man or group of men. I do not need to say again that my interest is only what I believe to be that of the public and the medical profession. Aside from this I have a sword that knows no brother.

JAMES F. ROONEY, M.D.

ALBANY, N. Y.

WHEN IS A DELEGATE NOT A DELEGATE?

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—When is a delegate not a delegate? When he is 129 147ths of one. This is the condition in the House of Delegates of the American Medical Association because of the fact that certain groups, called Scientific Sections, existing under Chapter XI of the Constitution, have the right to elect delegates to the House of Delegates to the number of *fifteen* which reduces the value of Representative Delegateship 15 147ths, or makes necessary the

pairing of the voting value of the equivalent of fifteen states, having one vote each, before representative delegateship begins to function. There are three other delegates, one each for the Army, Navy, and Public Health Service, who are appointed and who reduce, by 3 147ths, the value of representative delegateship but as these are necessary evils and it would be impracticable for them to be elected by their respective groups we will eliminate them from this analysis and confine ourselves to the "block of fifteen."

These Scientific Sections are a variable quantity; they may be attended by any one and the business deliberations, including the election of those delegates, may be participated in by "any fellow or associate fellow" who may happen to be in the Convention City at the time (Chap. XI).

The function of these Scientific Sections, I take it, is to afford the medical men of the country an opportunity to get the very best medical thought in crystallized shape at the annual meeting of the A. M. A. Good. But just what interests of these sections require this "block of 15" delegates in the House? Just why are not the duly elected representatives of the component State medical societies competent to safeguard the interests of the scientific sections which the House of Delegates had the power to create in the first instance and have the power to abolish at any time?

What is painfully apparent to the observer of medical society politics is the fact that here, at hand, and available to and malleable by the Administration, is a solid block of fifteen votes which can be influenced or coerced or hand-picked in support of a candidate for office or a policy with relation to legislation, such as compulsory health insurance, state medicine (health centers), maternity centers, national socialization of medicine (dept. of public welfare stuff) and medical reregistration acts.

Can't you hear those dear, gullible, honest doctors of ours gasp as, shocked and resentfully, they say: "Why, this man is talking about *doctors!* Surely they are above such manipulation of scientific medical societies to the purposes of mean politics!" Well, I am sorry to have to bruise their beautiful faith, but I would remind them of the attempt made to swing the New York State Medical Society over to the endorsement of compulsory health insurance; of the effort made by the Council of the same Society to secure the passage of the reregistration bill; of the effort made by the A. M. A. to impose compulsory health insurance on the profession through the appointment of a professional propagandist working in New York City. Details of the ins and outs of these maneuvers cannot be given here for want of space, but they can be had for the asking.

So, my dear, credulous doctors, it behooves you to re-form your opinion that "the king can do no wrong" and to realize that this "block of 15" is a menace to representative delegateship and to the best interests of the profession which it is supposed to serve. Apart from the fact that Drs. Phillips of New York and Billings of Chicago, were elected trustees by a majority, respectively, of 13 and 7 at the A. M. A. meeting in Boston over opposition which was based on their activity as propagandists of the very legislation which the rank and file of medicine realize is a menace—compulsory health insurance, State medicine and the like, it must also be borne in mind that 111 of the 147 delegates of the House passed upon the resolution which opposed the ambulatory treatment of narcotic addiction and that this action was quoted on June 29 in support of a demand for a New York City Health Department Ambulatory-Treatment-Prohibition ordinance, despite the fact that *not a single State medical society* had informed or instructed its delegates with regard to this subject and despite the further fact that the Governor of New York State had refused to sign a bill embodying that provision, because the rank and file opposed it as unreasonably restrictive of professional freedom and reasonably productive of a mushroom crop of drug-addict sanatoria in the State. . . . That A. M. A. Resolution was submitted by a Committee of Individuals and passed by a House of Individuals, fifteen of whom were elected delegates by the votes of not more than 5000 "fellows and associate fellows" in New Orleans at the 1920 meeting, and their voting power was equivalent to that of Arizona, Delaware, Florida, Idaho, Maine, Mississippi, Montana, Nevada, New Hampshire, New Mexico, North Dakota, Oregon, South Carolina, Rhode Island, and the District of Columbia—15 States with a population of 10,100,364, or New York and Michigan with a population of 13,953,241, or Pennsylvania and Ohio with a population of 14,479,411.

Then at the A. M. A. meeting in Boston, this year, the incoming president presented a resolution that $100,000 (of *your* money) be put in a fund and the *foundations* invited to contribute a like amount for "post graduate teaching." Are you so credulous, my dear doctor, as to believe that any one but the Foundation would boss that job? Do you realize that these 15 "scientific section delegates" had as much to say about that as the delegates from Massachusetts, Missouri, and Texas, representing 11,919,639 people, or the delegates from Arkansas, Colorado, Connecticut, Georgia, Louisiana, Maryland, Minnesota and South Dakota, with a population of 13,242,138 people?

Well, what are *you* going to do about this inequitable and potentially vicious situation between now and the next meeting of your State Medical Society which elects and has the power to instruct its delegates to wipe out this handicap to representative delegateship and the square deal in a National organization of Medical Men which is supposed to be representative of organized medical men in these United States but is not? Each delegate from a State Medical Society, being, as a matter of fact, but 129 147ths of a delegate, 18 147ths of his power vesting in a hand-picked group of Administration adherents, *three* being the personal appointees of the heads of the Army, Navy and Public Health Service, and *fifteen* being the choice (cumulatively) of not more than 5000 "fellows and associate fellows" present at the Boston meeting, and in attendance upon the section meetings at the time the "scientific section delegates" were chosen. It is nearly time there was a house-cleaning in the A. M. A. and Chapter XI of the Constitution amended to conform with equity.

JOHN J. A. O'REILLY, M.D.

405 UNION STREET, BROOKLYN, N. Y.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 11, 1921.

Post-Graduate Medical Education in Great Britain.—The carrying out of arrangements for making of London a great post-graduate medical center lags sadly. A general scheme for providing facilities calculated to attract post-graduate medical students to London has been sketched for some little time, but further progress is extremely slow mainly because of lack of funds. Dr. Addison, the late Minister of Health, appointed in January last a committee to investigate thoroughly the entire subject. The committee included Sir Wilmot Herringham, Sir George Makins, and Sir George Newman, besides several eminent business men. Its report was issued a week or two ago. The main recommendation advanced by this committee is that a Central Post-Graduate Hospital and School be established to be devoted to post-graduate work alone. According to the report the hospital should contain, at least, 300 beds and its equipment should be complete and thoroughly up-to-date. The point that a fully developed out-patient department is an essential feature of such a school is insisted upon. Moreover, the great special hospitals of London would be associated with this school, and the institution of a central office to link up post-graduate study in this country with that of Europe and America is suggested.

A further notable recommendation is the establishment of an institute of state medicine in which public health post-graduate work should be concentrated. The scheme in its entirety as outlined in the report would cost about £28,000 a year. As constituent parts of the University of London, the school and institute would be eligible for inclusion in the list of institutions subsidized by the treasury through the University Grants Committee. It may be said that it is not proposed to ask for any aid from local rates. It seems somewhat extraordinary that the money should not be forthcoming for the completion of a scheme of this nature. It is a fact that the wealthy philanthropists of Great Britain are curiously averse to contributing largely in support of schemes likely to benefit health generally. If London were the great medical center it should be it would attract students from all parts of the world and give an immense impetus to medical training and the improvement of medicine and surgery with consequent obvious advance in methods for saving and lengthening life. If the suggestions contained in the report are not acted upon promptly the time for doing so with good chance of success will have gone never to return. Vienna and Berlin are making every effort to recapture the positions they held before the war as the principal post-graduate centers of Europe.

British Congress of Obstetrics and Gynecology.—The first British Congress of Obstetrics and Gynecology was held in Birmingham on June 3 and 4, last. Before the reading of papers attention was called to a resolution which was to be proposed, namely: "That in the opinion of this meeting operations by the abdominal route are quite unnecessary for the treatment of genital prolapse." It was thought by certain objectors that the best interests of the profession would not be served by placing this resolution before the meeting and the proposer then withdrew his motion. Dr. Fothergill opened a discussion upon the end-results of vaginal operations for genital prolapse. He described briefly the steps by which he was led to adopt the technique of vaginal operation he now employs and provided figures showing the results of this operation. Dr. Lacey and he inquired of women operated upon by this method, and in the replies covering a period of four and one-half to seven and one-half years from the date of the operation, 150 women stated without qualification that they were cured, whilst six were not. In conclusion Dr. Fothergill observed that, inasmuch as vaginal operations afford for all varieties of prolapse, treatment that is efficient and permanent, that does not prevent pregnancy, and that stands the test of parturition in a large proportion of cases, abdominal intervention is unnecessary and undesirable. The latter adds to the risk and discomfort of the patient and involves more trouble and loss of time to the operator.

Dr. Lacey strongly corroborated all of the previous speaker's statements, and said that it was unnecessary and superfluous to operate for genital prolapse by the abdominal route.

Dr. Herbert Spencer of London said that statistics have been described as "lies expressed in terms of figures." He might also have referred to the description of statistics given by the late Professor Black of Glasgow that like sausages they depended largely upon the old woman who made them. Dr. Spencer went on to remark that while he was not able to put forward figures himself, he was, on the whole, fairly well satisfied with vaginal operations for prolapse, and he agreed with Dr. Fothergill that abdominal operations were not necessary. Dr. T. G. Stevens of London agreed that vaginal operations were the most satisfactory by far, but drew attention to risk of secondary hemorrhage after this operation. Dr. A. G. Giles, London, said that symptomatic cures were often not anatomical cures. The converse might also be true. No operation could be curative in every case, and for this reason the result should not be guaranteed. In his experience 96 to 97 per cent. of all cases were cured after the operation. With regard to Dr. Fothergill's operation he thought that to say it was the only method was rather begging the question. There were over 150 different methods of suturing the abdominal wall, and one writer had stated that every one was as good as any other. In the same way he could claim equally good results in the treatment of prolapse from hysteropexy combined with a vaginal plastic operation. Dr. Walter Swayne of Bristol said that he was averse to abdominal methods.

Prof. Henry Briggs of Liverpool said it was incorrect to assume that one method only could cure prolapse, or that one type of suture material was the only material admissible. Dr. R. H. Paramore of Rugby drew attention to the complete absence in the case of previous speakers of any reference to the levator ani in the cause of genital prolapse. He was under the impression that myor-

rhaphy of the levatores ani was most important and was surprised that no mention had been made of this procedure. Prof. Gammeltoft of Copenhagen expressed surprise at not having heard greater reference to the levatores ani. Dr. Miles H. Phillips of Sheffield said he had in a large measure adopted Fothergill's practice, but he had not cured all his cases and wondered if any one method would cure them all.

Dr. I. W. Eden said it was important that we should adhere to the principle of selecting the ideal operation for each individual case.

Dr. E. J. Browne of Edinburgh read a communication upon the pathology of syphilis of the new-born. The speaker drew attention to the failure of the Wassermann reaction in the diagnosis of fetal syphilis, since on many occasions it was repeatedly negative in both mother and child when undoubted evidence of the disease existed on pathological investigation of the organs. The viscera which give the most important evidence are the liver, spleen, kidney, suprarenals, and lung. The placenta may or may not show lesions, and Dr. Browne had been unable to demonstrate the presence of the *Spirocheta pallida* in any of the placentæ that he had examined. Dr. Carlton Oldfield of Leeds thought that one very important fact was that the diagnosis of syphilis as a cause of still-birth could not be made without a very exhaustive examination.

Professor Gammeloft agreed with Dr. Browne that neither examination of the placenta nor the Wassermann reaction could be relied on in the diagnosis of fetal syphilis. He considered, however that endarteritis of the vessels of the umbilical cord was a very important diagnostic point.

Dr. Eardley Holland said that he had been interested for some time in the still-birth problem, but his investigations had been confined to viable and not macerated fetuses. The problems he had set out to investigate were two, viz., the incidence of fetal syphilis as a cause of stillbirth and how to diagnose syphilis in the absence of spirochetes. Formerly the percentage of fetal deaths due to syphilis was thought to be as high as 50. Lately, however, it had been proved by Whitridge Williams and others that 15 per cent. was nearer the mark. His own investigations in 37 cases had been confined to the following points: (1) The Wassermann reaction in the mother; (2) the presence of chondroepiphsitis in the fetus; (3) enlargement of the liver; (4) enlargement of the spleen; (5) examination of the placenta. In the case of the Wassermann reaction he had found it positive in the mother in 97 per cent. of the cases investigated. Chrondoepiphsitis was also present in 97 per cent. of the fetuses. The spleen was enlarged in every case and the liver in nearly all cases. A difficulty arose with regard to the weight of organs, in that at present, there is no absolute standard. It was necessary to consider, therefore, the ratio of the weight of the liver and spleen to that of the fetus and this was the line he was now taking. If both organs were enlarged Dr. Holland considered it a very important diagnostic point. The largest spleens occurred in cases of general edema of the fetus. As regards the placenta, naked-eye appearances were of no value. Typical microscopic appearances, however, were present in 67 per cent. of the cases examined. In all these spirochetes had been demonstrated in the tissues. In the case of 263 still-born fetuses where spirochetes could not be found, 25 were considered worthy of detailed investigation. Five of these showed certain evidence of syphilis, in spite of the apparent absence of spirochetes.

Dr. G. L. Strachan agreed with Dr. Browne as to the difficulty of diagnosing fetal syphilis from an examination of the placenta. He considered, however, that the examination of the umbilical cord was most important, even if the Wassermann reaction was negative. Spirochetes were demonstrable in the arterial walls, as well as endarteritis. From the examination of 100 cases of still born fetuses, he believed that syphilis was a very rare cause of antenatal death. Dr. Walter Swayne, from an investigation of the Wassermann reaction in the case of new-born infants, was of the opinion that syphilis is much less common as a cause of infant death than is suspected. Certainly a positive Wassermann reaction is much more difficult to obtain in new-born infants, even if obviously syphilitic, than in adults.

Obituary.—Sir George Henry Savage, consulting physician for mental diseases, Guy's Hospital, died in London on June 20. He was seventy-eight years of age and graduated at London University in 1867. He was lecturer in mental diseases at Guy's Hospital, consulting physician to that hospital and to the Earlswood Asylum, an examiner in mental physiology to London University, and the author of a manual on insanity.

Henry Work Dodd, F. R. C. S. (London), consulting surgeon to the Westminster Ophthalmic Hospital, died after a long illness in London on June 30. He held many hospital appointments and was a somewhat voluminous writer on ophthalmology.

Progress of Medical Science.

5. A Nutrition Campaign in Rochester. William R. P. Emerson.
6. Significant Reactions of the Arterial Tension. Manifestations of the Angio-Kinetic Energy Clinically Observed and Interpreted. Claës Julius Enebuske.

3. Empyema. Report of Cases Occurring at the Boston City Hospital, Assigned to the Writer in 1920.—J. O. Hubbard reports observations made on 35 cases of empyema, of which four died. Death was due in one instance to bad judgment in selection of the time for operation, in the other three cases to erysipelas, auricular fibrillation, and septic absorption, respectively. The different bacteria found on culture were the *Streptococcus hemolyticus* in 13 instances, pneumococcus Type I in eight cases; in the remaining cases the infections were scattered. When the writer began he thought he could tell from the gross characteristics of the fluid in the chest the particular germ which was causing the infection. He soon learned that he was wrong and that by culture alone was it possible to tell. Of the cases which recovered 20 had no pneumothorax; the duration of time elapsing between operation and

x-ray ranging from twenty-two days to eight months. The type of operation apparently had little to do with the presence of pneumothorax. In 32 of the cases there are records of the type of operation. Of these 32 cases, 11 had primary rib resection and nine a catheter insertion only. Of these, seven recovered and two died, an interesting showing for nothing more than drainage through a catheter. The fact that several cases returned with a broken down wound and discharge at periods of five to nine months after discharge shows the folly of trying to draw conclusions about end results until many months have elapsed. As the result of his experience certain very definite ideas in regard to treatment have suggested themselves to the writer. In the first place empyema is no longer the emergency it was once considered. It is best not to operate for several days, but to try the effect of repeated aspiration and later to put a catheter into the chest through a trochar, under gas oxygen anesthesia. It is not necessary to work hard or to bother the patient much with attempts to keep a tight joint for long. Cases that will not drain in this way require rib resection. Irrigations and installations are of benefit if proper technic is carried out.

4. The Present Status of the Radiation Treatment of Hypertrophied Tonsils.—Herman A. Osgood asserts that the present status of radiation treatment for hypertrophied tonsils is that of an optional method to surgery. It is not a replacement of tonsillectomy. It is a method which can produce definitely an induced atrophy of hypertrophied tonsils without hemorrhage, discomfort or loss of time. It does not sterilize. Its effect on the bacteria and crypts is that of mechanical drainage. As compared with tonsillectomy it is the method of choice in cases in which complications increase the operative risk. Its disadvantage is the time required for results, and the necessity of selecting suitable cases. It is a method which has given very gratifying results clinically thus far, but has not been proven by the test of time. The dangers of radiation are (1) the possibility of *x*-ray dermatitis; (2) the possibility of other than *x*-ray tissue being affected by the ray; (3) the possibility of late degenerative changes in the skin. All of these objections may be overcome by proper technic.

4. The Use of Experimental Psychology in the Practice of Medicine.—Edmund Jacobson states that, while every practitioner makes use of some type of psychology, whether he knows it or not, his knowledge of the mind does not come from the laboratory, but is popular rather than scientific. Modern instruments of precision for measuring mental processes might be simplified and applied to clinical use. For instance, electrical stimulation may move a muscle where willimpulse fails. On this basis it is possible to determine whether fatigue is in the muscle or in the nervous system. There are instances where a graphic registration of stereotypy of movement would seem to have a certain diagnostic value. The writing machine of Kraepelin and the simpler device of Henry have been recommended for measuring voluntary motor activity. In melancholia a rapid decrease of pressure and speed has been noted, while in manic excitement the opposite seems to be characteristic. In catatonia, even when letters are made correctly and well, it seems characteristic that the time intervals are markedly irregular. This trait seems to come and go with the phase of catatonia, and would appear to be a fine sign pathognomonic of this condition. Some of the problems of general medicine that may be attacked by instruments and methods such as have been referred to are the effects of suggestion, controlled data as to the faith of the patient that he will get well, emotion, the origin of subjective symptoms, the influence of work and rest on the course of disease, the effect of mental influences on particular diseases, and the question as to whether functional disturbance can lead to organic disease, and in what way, the study of mental conditions in individual diseases, etc. The writer ventures to express the hope that with the future development of experimental psychology applied to medicine, a new period of treatment may gradually arise, not merely for functional, but also for organic conditions; a period when the internist will not be content with considering the nervous and mental aspects of disease utterly out of his domain; a period in which it will not be considered sufficient to doctor the body alone, or, in other instances, the mind alone; but rather the assumption as a rule that, with every patient and in practically every malady, there is both a physical and a mental side that may demand delicate attention. From this point of view therapeutics in general should have a combined physical and mental approach.

5. Determination of the Basal Metabolism as a Method of Diagnosis and as a Guide to Treatment.—James H. Means. (See MEDICAL RECORD, June 18, 1921, xcix, 25, p. 1078.)

6. The Basal Metabolism in Fever.—Eugene F. DuBois. (See MEDICAL RECORD, June 18, 1921, xcix, 25, p. 1078.)

9. Quantitative Estimate of Total Protein in the Cerebrospinal Fluid.—James B. Ayer and Harold E. Foster have made more than 2100 quantitative tests of the protein in the spinal fluid from approximately 800 patients. The results of 429 of these tests are tabulated in the present study. They were not chosen to conform to any preconceived idea, but only if the history, symptoms, and laboratory findings permitted of a fairly definite and accurate diagnosis. The method of Dennis was used and abundantly justified the extra amount of time it consumed. The quantitative method serves to control quicker and less accurate methods and is a means of drawing the line more closely between the normal and pathological condition of the spinal fluid. The method is of value in following the protein content of fluids from patients under treatment for neurosyphilis. It has been found that protein begins to fall early under treatment in all forms of neurosyphilis except paresis; in the latter it may even increase though the cell count is dropping. In studying fluids from different loci of the subarachnoid space, especially in the early diagnosis of spinal subarachnoid block by tumors and other pathological states, not infrequently a fluid is obtained by lumbar puncture which is slightly abnormal in protein content, but which might, and frequently does, pass as of no significance. When, by means of cistern puncture, the fluid above is compared with that below, a difference of more than the slightest degree is found to be of importance. Such comparative readings are of great value in the diagnosis of cord tumor, as significant as, and of more practical value than, the dramatic xanthochromic fluid with massive coagulation. For certain disease entities the quantitative protein estimations give fairly constant readings. The average normal quantity of protein in the spinal fluid is within the limits set by other observers. Any total protein quantitation above 40 mg. per 100 c.c. is distinctly pathological. In the syphilitic group of cases higher readings are associated with acute meningitic types (exudate in origin) or with the more profound degenerative types, such as paresis

(transudative in origin). Several groups of cases in which the spinal fluid has been said to be negative are shown to be abnormal on careful protein determination. Thus of a group of cases presenting vascular hypertension, 30 out of 39 showed hyperalbuminosis. In these cases there is usually to be found protein excess which, because of lack of cells, is of transudative origin. This is a point but seldom emphasized, and one of considerable diagnostic significance. In a similar manner a limited number of cases of purely degenerative character, such as multiple sclerosis and paralysis agitans, have presented increased protein. Fluids from brain tumors and abscesses are not necessarily "negative," but may present considerable protein excess. As is well known the acute forms of meningitis yield a very great amount of protein, but it was not realized by the authors until the present method was employed that a typical acute meningitis might be associated with a comparatively slight protein output, even in advanced stages of the disease. The amount of protein obtained in tuberculous meningitis agrees with preconceived ideas that the protein is moderately increased, but less than in the pyogenic forms. During the course of these observations it was clearly demonstrated that in cases in which fluid was withdrawn at an interval of a few days, the second fluid regularly presented lower readings. If the interval was increased to a week or more, this was not the case.

2. The Capillary Pressure and the Circulation in Shock.—Leonard Hill and James McQueen, as a result of experimental work, state that normally the loss of pressure of the blood in traversing a capillary area is very small. L. Hill found a very small pressure was required to propel the blood along the capillaries in the web of the amputated foot of the frog. The kinetic energy of the flow in the capillaries naturally is correlated exactly to the frictional resistance of the blood inside the capillary. In normal conditions both the kinetic energy of flow and the frictional resistance due to viscosity are very small. Any increase in viscosity has, therefore, a very great slowing effect on the blood current because the kinetic pressure of blood flow is at most a very few millimeters of mercury. In normal conditions of health the body maintains the viscosity just as constant as it does the osmotic pressure or the hydrogen-ion concentration of the blood. Hill has shown that the capillaries that have blood in them are capable of taking up much more blood by dilatation; that there are numerous capillaries not filled at all, and that there are anastomotic channels whereby pressure is easily and quickly transmitted between the small arteries and the veins. In surgical shock blood slowly concentrates in the capillary area and the return blood to the heart is a mixture of blood of more normal concentration passing by the direct anastomotic channels and concentrated blood returned from the capillaries to the veins. Viscosity of the blood in the capillaries may be overcome by dilution with other blood or gum saline mixtures and the pressure in the arterial tree raised by the injection; both factors tend to remove the stagnation. The blood diluted with donor's blood or gum saline has the easy path of return to the heart via anastomotic channels, and is not compelled to force its way through the capillaries that are already choked with concentrated blood. The pressure rising from the injected blood or gum saline is transmitted to the capillary area, dilutes the concentrated blood in the capillary area, restores it to a more normal viscosity, reoxygenizes the tissue cells and prevents the increasing loss of fluid by imbibition and permeation. The accurate measurement of capillary blood pressure then throws light on stasis. Low arterial blood pressures are dangerous because the capillary kinetic energy of blood flow is very small with normal arterial blood pressure. There is a very small margin of safety in the capillary area.

4. Effects of Hot and Cold Applications to the Surface of the Body on the Temperature of the Muscles, Liver, Kidneys and Brain.—J. J. R. Macleod and N. B. Taylor have shown in a previous communication that the application of heat to the surface of the thigh in a rabbit caused an immediate rise in the temperature which spread laterally for about 20 mm., and penetrated into the muscles for about the same distance. When heat was applied to the surface of the abdomen, at a temperature difference of 15° C. and over a broader area, temperature changes were observed to a depth of 75 mm., the lateral spread being 20 mm. It was shown that the rise of temperature was mainly dependent upon actual conduction of heat through the tissues, and not due to vaso-dilatation. In the present communication the writers report further observations of the same general nature. The effect produced on the subcutaneous temperature by local cold is very marked, and is immediately evident. The lateral spread of cold conforms very well with the results obtained for the lateral spread of heat. As might be expected from its greater vascularity, the changes in temperature in the liver, for equal differences in temperature between the applicator and the body, are decidedly less than in muscle when heat is applied. The effects of cold are much more marked. Although this is mainly due to the much greater difference between the temperatures of the applicator and the body, it would appear that there is some critical temperature difference below which the cold has a progressively greater influence. This may be due to vaso-constriction. For the kidney the results in the main were the same as for the liver, at least for heat. The temperature in the kidney never rose more than 0.3 C., even when the applicator was 12 C. higher than the body temperature. The conclusion from these experiments is that it is not possible to cause any significant change in temperature in the liver or kidney by the local application to the surface of the body over either viscus of applicators that are 10° or 12° C. warmer than the viscus. Similar experiments carried out on the brain showed that heat penetrated from the surface into the brain much more than it did in the case of the liver or kidney, although apparently not so much so as into the muscle. When lower temperatures were used the fall in brain temperature became very marked indeed. A knowledge of this fact is of importance therapeutically.

1. The Colon and Colitis.—Lord Dawson of Penn points out the great influence for weal or woe that the colon exerts in our daily lives. It is an organ with a highly developed functional activity closely linked up not only with other portions of the alimentary tract, but with the high nervous centers. An acute attack will sometimes begin quite definitely in the upper alimentary tract with symptoms quite suggestive of protein shock. Again the order is reversed and colonic manifestations are followed by gastric symptoms. Colitis is one phase of a disturbed digestion in which stomach, duodenum, intestine, pancreas may all play a part. Side by side with the stress and strain of modern life which impair function we find food and methods of feeding that at the same time overtax it. The food of people to-day is in many respects open to more criticism than in former days. Many of our

foods show a vitamin deficiency which means not only impaired metabolism, but appears directly to damage digestive function itself. In discussing the subject of intestinal stasis and toxemia Lord Dawson insists on the important detoxicating function of the liver, and refers to the observations of Widal and his coworkers on the "hemoclasic crisis" or the changes—leucopenia, fall in blood pressure, and loss of coagulation—which precede the manifestation of protein shock; normally the liver prevents proteins having this effect from entering the general circulation, and therefore no "hemoclasic crisis" follows digestion; but with hepatic insufficiency these changes occur, and in this connection it is mentioned that Widal, Abrami, and Iancovesco have adopted as a test for the functional activity of the liver an examination of the "hemoclasis crisis" after drinking a tumbler of milk. The condition commonly known as "chill on the liver" is compared to anaphylactic shock, and a resemblance is traced between asthma and colitis, which suggests that some attacks of colitis without obvious cause may be anaphylactic in origin. Discussing the subject of treatment, Lord Dawson says that the appendix is rarely the primary focus, and when inflamed becomes so concomitantly with the colon; its removal seldom benefits patients with colitis. Further, a wise caution is thrown out as to the significance of anatomical abnormalities revealed by *x*-ray photographs; various displacements may exist without symptoms because the really important factor is the muscular efficiency of the bowel, and hence ingenious operations for various ptoses may prove disappointing when the essential defect is muscular failure and not the obvious visceral displacement. Complete colectomy the author regards as disappointing, though exceptional successes are admitted. The indications for colectomy would seem to be: 1. Where the motility of the colon is so spent that all other measures fail to prevent stasis within it. 2. Where the colon is so damaged in its defenses that, in spite of every effort to keep it cleansed, toxic products get through in such abundance as to ruin the health of the patient. But here, too, there is danger that the second line of defense in the liver may be damaged also. Hemicolectomy, however, is on a different footing. The operative risk is small, and if it fails in its object there is little danger of the patient's condition becoming worse. If the failure of function is in the proximal end the prospect of success should be good, especially if the ileocecal valve is preserved in the implanted portion. Colotomy is likely to be more efficient in cases in which the distal colon shows muscular insufficiency.

3. The Intravenous Administration of Calcium Acetyl Salicylate.—Archibald Campbell has employed intravenous injections of calcium acetyl salicylate in a number of conditions where other remedies have failed to bring alleviation. They include sciatica, acute rheumatism, tabes dorsalis, interstitial keratitis, acute iritis, gonorrheal synovitis, arsenical neuritis, dysmenorrhea, and severe headache of doubtful causation. In all, 55 cases have been treated in this way. Pain is relieved in half to three-quarters of an hour and the effect persists for several hours and in some cases for days. The technique is simple. A 1-gram tablet is dissolved in 10 c.c. of distilled water by boiling in a test tube in order to insure sterilization; the solution is then cooled and injected into a vein with a glass syringe. Calcium acetyl salicylate produces a greater and more immediate relief of pain than aspirin administered by mouth, and its administration is not harmful. It acts beneficially in many instances where other remedies have failed.

1. The Breathing of Air of Lowered Oxygen Tension as a Test of Circulatory Function.—Alfred Stengel, Charles C. Wolferth, and Leon Jonas have attempted to determine the usefulness of the rebreathing apparatus for clinical purposes in hospital work, especially with reference to its value in estimating circulatory efficiency. A number of studies were made on presumably normal individuals, also convalescent hospital patients who had no anemia, lung disease or apparent circulatory deficiency, as well as a few patients with pneumokoniosis and a number with varying degrees of circulatory inadequacy. The rebreathing apparatus used was similar to the one described by Henderson in the *Journal of Physiology*, 1919, liii, 181. As was to be expected, moderately advanced pneumokoniosis did not interfere materially with the ability of the individual to compensate for low oxygen. Some of the results in cardiac cases were unexpected. If the heart always played an important part in the compensation for anoxemia in all the cases presented an early breakdown would be expected in the rebreathing test. Early failure did, indeed, occur in two of the five cases observed—notably in one with advanced decompensation. The writers conclude that, while the rebreathing test may offer a good indication as to the general fitness of the individual, the part the heart plays in any case in the adaptation anoxemia is particularly difficult to evaluate because there occurs a coordination of several mechanisms, some of which are known, doubtless others unknown. The variations in response to the anoxemia produced by the rebreathing apparatus, among cases with, at most, narrow margins of cardiac reserve, appear to justify the conclusion that the test does not furnish a trustworthy index of cardiac function.

10. Influenza and Epilepsy: Further Studies upon the Relation of Mental Disease and Influenza.—Karl A. Menninger, from a study of pertinent literature and clinical material afforded by the epidemic of influenza of 1918-1919, summarizes his observations as follows: 1. The effect of influenza upon idiopathic epilepsy is not uniform. 2. Beneficial influence is occasionally observed; seizures are perhaps usually absent during the febrile state and in some instances occur with decreased frequency after the acute infection. There are no cases on record in which influenza has induced an entire cessation of epileptic attacks once instituted. 3. Deleterious influence is more frequently observed manifested in various ways. 4. Seizures may occur with increased frequency following influenza, both as compared with short periods and long periods of time prior to the acute infection. 5. The character of type of the seizures may change subsequent to the influenza, in addition to or independent of the increase in frequency. 6. Epilepsies whose manifestations have long lain latent may be incited to renewed activity by the attack of influenza. 7. Psychoses may be precipitated in epileptics by influenza, as in non-epileptics. 8. Epileptiform syndromes which resemble typical idiopathic epilepsy, except that recovery usually occurs shortly, are occasionally evoked by influenza. Probably we should regard these as recoverable or "reversible" types of idiopathic epilepsy, the product of influenza and a (possibly) susceptible brain. Possibly they are manifestations of multiple miliary (encephalitic) hemorrhages. 9. The majority of epileptic patients observed did not exhibit any alteration in their disease. 10. The effect of epilepsy on influenza was observed to be a lowered resistance, and hence increase morbidity and mortality rates (as compared with normal persons). 11. Influenza thus appears to exhibit in the case of enilepsy the properties previously demonstrated to be operative in the case of psychoses associated with influenza—namely, creation, precipitation, aggravation, and amelioration.

Book Reviews.

CHIRURGIE DE L'ŒIL ET DE SES ANNEXES. Deuxième Edition Refondue. Par F. TERRIEN. Paris: Masson & Cie, 1921.

THE first edition of this work appeared in 1902 so that the present volume is practically a new book. The earlier edition was part of a system of medicine and surgery and its successor has nearly 200 more pages (620 all told) with nearly 500 illustrations. There are two volumes in one, devoted respectively to the globus oculi and adnexa. In the first we find chapters on operative surgery of the cornea, sclerotic and iris, with three entire chapters on cataract operations and one on the surgery of the bulk as a whole. In the second part there are chapters on the surgery of the muscles, the conjunctiva, lacrymal apparatus, orbit, and eyelids. In addition there is an introductory chapter and an appendix, the latter dealing with lumbar puncture in eye diseases and visual disorders due to hypophysis tumors.

DIE CHIRURGIE DER PERIPHEREN NERVENVERLETZUNGEN mit besonderer Berücksichtigung der Kriegsnervenverletzungen. Von Privatdozent DR. WALTER LEHMANN. Berlin und Wien: Urban & Schwarzenberg, 1921.

THIS volume comprises 269 pages and 66 illustrations including colored and multicolored plates. There is a brief introduction by Professor Stich of the Surgical Clinic at Göttingen, to whom the author is an assistant. The eleven sections of the book (comprising 38 chapters) are devoted respectively to etiology and symptomatology, pathological anatomy, diagnosis, prognosis and operative treatment of peripheral nerve injuries, technics of resection and suture, repair of great nerve defects, early recoveries, special lesions of cranial nerves, brachial plexus and lumbosacral nerves with resulting pareses. The exhaustiveness and conciseness of the book are well matched, and the arrangement of the matter as shown in the table of contents leaves nothing to be desired. Finally the analytical index does not duplicate but supplements the table of contents.

GRUNDRISS DER HISTOPATHOLOGIE DER HAUTKRANKHEITEN. von Dr. WALTER FRIBOES. Professor der Dermatologie und Direktor der Dermatalogischen Klinik an der Universität Rostock. Leipzig: F. C. W. Vogel, 1921.

THIS volume of 208 pages has 105 illustrations of which many are in colors and is therefore virtually an atlas. The subject matter is almost entirely personal, based on the author's own material as shown by the silence of the book on the earlier work of Unna and others. The author writes primarily for the students in the aim of connecting the histology of dermatoses with clinical phenomena. Hence the text while in part a commentary on the pictures also comprises a brief clinical description of the various affections. In reading the preface we note that the only illustrations borrowed for the book are a few supplied by Professor Jadassohn, of rare dermatoses not represented in the Rostock collection. An English edition of this work would doubtless be appreciated by the numerous students, under- and postgraduates, of the United States and Great Britain and her dependencies.

KOMPENDIUM DER KINDERHEILKUNDE mit besonderer Berucksichtigung der Sauglingskrankheiten Von Professor Dr. ALBERT NIEMANN. Berlin: S. Karger, 1920.

THIS work was written in part before the war, and was completed at the close of the war. Its object is to give up-to-date information concerning diseases of the newly born with especial reference to congenital and acquired diseases. In a very interesting chaper on infantilism the condition is described by the author as hypotrophy. Congenital heart, spastic diplegia, rickets, and exudative diathesis (which has been elaborated by Czerny) are described in detail. In the second portion of the book we find many interesting points concerning infant feeding and practical data for the general practitioner. The author figures the amount of nutrition in calories. Regarding the special forms of feeding we find malt soup and buttermilk soup frequently advised. The vitamine question is considered in the chapter on feeding. The book is devoid of theories, and the author does not waste much time in giving literature. There is a distinct absence of illustrations. We are so accustomed to seeing books on children illustrated that the absence of the same is noticeable.

HANDBUCH DER SEXUALWISSENSCHOFTEN. Mit besonderer Berüchsicktigung der Kulturgeschichtlichen Beziehungen. Unter Mitwerkung von Dr. med. et phil. G. BUSCHAN in Stettin, HAVELOCK ELLIS in London, Professor Dr. SEVED RIBBING in Lund, Dr. R. WEISSENBERG in Berlin, und Professor Dr. K. ZIELER in Würzburg herausgegeben von Dr. ALBERT MOLL. Geh. Sanitätsrat in Berlin 2 auflage. Leipzig: F. C. W. Vogel, 1921.

THE author-editor candidly states that this edition is only a reprint of his first edition of 1911, with the exception of an appendix on the gonads which occupies but sixteen pages. The original edition having become well known to the reading public, there is nothing for the reviewer to add. Dr. Moll states that there is practically nothing to incorporate into a second edition, but even had anything accumulated, tne war would have prevented a revision.

GENERAL PATHOLOGY. By Dr. ERNST ZIEGLER, Professor of Pathological Anatomy and of General Pathology in the University of Freiburg in Breisgau. From the Eleventh Revised German Edition (1905). Revised by DOUGLAS SYMMERS, M.D., Director of Laboratories, Bellevue and Allied Hospitals. Price, $7.00. New York: William Wood & Co., 1921.

THERE are those who assert that tissue pathology is a finished subject so far as our present methods will permit us to go. A perusal of the list of changes which were found necessary in the preparation of this edition is ample demonstration of the falsity of any such accusation. The statement may well be true in a limited sense and with a special application to certain problems, but there is still room for the careful observer and earnest student to add to our information on this subject. Dr. Symmers has performed a valuable service in revising this work and has enriched it with the results of his own large experience. He has also added a number of illustrations from the service at Bellevue Hospital. The original arrangement of the book has been preserved. We surmise it will be helpful not only "to the medical profession generally and especially to students of medicine," but also to pathologists who inevitably tend to become interested in special pathology and so need the broadening influence of a work of a more general type.

AMEBOID MOVEMENT. By ASA A. SCHAEFFER, Ph.D., Professor of Zoology, University of Tennessee. Princeton, N. J.: Princeton University Press, 1920.

THIS subject has interest for the physiologist, the psychologist, and the general biologist and evolutionist as well as for the student of medicine. To the medical investigator the movements of the white blood corpuscles and the values of the ciliated cells, there is a great suggestion. Further, the determination of movement in orderly paths in organisms in which orienting organs are absent or not functioning, suggests interest in cell movement and circulation in structures such as ciliated membranes or even the organ of Corti.

LEITFADEN DER NEUROLOGISCHEN DIAGNOSTIK. Eine Differential diagnose aus dem führenden Symptom für praktische Aerzte und Studierende. Von Dr. KURT SINGER, Nervenarzt in Berlin. Berlin and Vienna: Urban & Schwarzenberg, 1921.

THIS volume of about 200 pages comprises 18 chapters devoted to the following subjects: paralyses, sensory disturbances, muscular atrophy, disturbances of reflexes, disturbances of gait, spasms, convulsions, tremor, neuralgias, headache, vertigo, unconsciousness, speech disturbances, pupillary disturbances, disturbances of vision, ocular pareses, nervous manifestations of visceral origin—chiefly cardiac palpitation and vomiting—and nervousness. This arrangement is highly practical and suggests that of works like Cabot's "Differential Diagnosis by Case Histories," in which the dominant symptom is used as a base of classification. The present volume is much too concise, however, to permit the use of illustrative cases.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Twenty-second Annual Meeting Held in Washington, D. C., June 3 and 4, 1921.

First Day—Friday, June 3.

President's Address.—Dr. JOHN C. HEMMETER of Baltimore delivered this address, taking as his title: "The Human Constitution and the Perspectives in Pathogenesis and Therapeutics of Today." (See page 223.)

Dr. C. E. DE M. SAJOUS of Philadelphia expressed his admiration of the scholarly and elucidative address of Dr. Hemmeter who typified, owing to his broad biological knowledge, the kind of worker needed to raise medicine eventually to a truly scientific plane. Such a man, a trained physiologist, biochemist, histologist, and clinician, all in one, would be able, if endowed with a philosophical mind, to coordinate, analyze, and synthetize sound data from various branches of medical knowledge and evolve new resources of great value to suffering humanity. The socalled "authorities" of older days who, though working in a restricted clinical field, thought themselves all-wise, and acted accordingly, were, fortunately for humanity, rapidly disappearing. Laboratory investigators were likewise losing their hold upon the profession, owing to the discordance of their own results and the freedom with which they presumed to criticise, often with obvious ignorance of clinical facts, the observations and conclusions of practitioners. The tendency of the day was toward harmony and constructive work with all branches of medicine, practical and auxiliary, as sources of information. A striking example of the advantages of this attitude was afforded by the present views concerning the functions of the adrenals. Although these conceptions were about as divergent and mutually antagonistic as the physiologists who described them, all could easily be shown to harmonize when interpreted from the standpoint of broader knowledge. The various branches of medical learning had become during the last seventy years replete with sound and unused data which, inventoried, grouped, scrutinized, and harmonized, would reveal more new truths than the present day narrow-gauge, discordant, and random methods of research would evoke in decades. It was here that broadly equipped men such as Dr. Hemmeter —constructive philosophers of a high type—were needed.

Symposium on Alcohol.

History of Alcohol as a Substance for Human Consumption.—Dr. JOHN C. HEMMETER of Baltimore opened the Symposium with this paper. (See page 271.)

The Pharmacology of Alcohol and Its Influence on Metabolism.—Dr. JACOB DINER of New York presented this as the second contribution to the Symposium. (See page 273.)

The Effect of Alcohol on the Gastrointestinal Tract.—Dr. WILLIAM J. MALLORY of Washington followed with this paper. (See page 275.)

The Effect of Alcohol on the Therapy of Internal Diseases.—Dr. CHARLES G. STOCKTON of Buffalo presented this communication. (See page 277.)

The Effect of Alcohol on the Heart and Blood Vessels.—Dr. LOUIS FAUGÈRES BISHOP of New York sends this paper. (See page 279.)

The Effects of Alcohol Upon the Endocrines.—Dr. CHARLES E. DE M. SAJOUS of Philadelphia sends this paper. (See page 280.)

Alcohol in Surgery.—Dr. ROBERT T. MORRIS of New York presented this communication. (See page 284.)

Influence of Alcohol on the Cerebral and Peripheral Nervous System.—Dr. W. M. BARTON of Washington, D. C., read this paper.

The Relation of Alcohol to Modern Health Ideals.—Dr. EUGENE LYMAN FISKE of New York presented this paper, which consisted of a statistical study of the relation of alcohol to health and disease. He said it had been a hard pull to drag the problem of alcohol out of the arena of politico-religious discussion and subject it to practical analysis. It had been the widespread dissemination of information derived from thoroughly impartial sources expressing the liability that alcohol imposed upon the groups that used it that had brought man to the point of deciding that it should be taken from the table and placed on the drug shelf. In fact, alcohol had even been denied a certificate of character as a drug. It had fallen to a lower level than opium. Personally, Dr. Fiske said he had no sympathy with the characterization of alcohol as a demon or as an occult malignant influence. It had seemed to him a very simple problem in toxicology. From the evidence that we had from the laboratory as to the disturbing effects of alcohol on the cerebrospinal mechanism added to the evidence which we had from the clinic as to the obviously destructive effect of alcohol in heavy dosage, which it was the ultimate fate of a considerable proportion of alcohol users to receive, it might fairly and honestly be stated that there would be every reason to expect that an analysis of the mortality experience among large masses of individuals classified as moderate and temperate users of alcohol would show in the final analysis a heavier death rate than that experienced among individuals similarly situated, except for the use of alcohol. This was exactly what was shown by the records of forty-three insurance companies. Other statistical data showed a larger percentage of psychoses among the users of alcohol than among the nonusers. In a questionnaire sent out from Washington during the war asking "What is your experience as to the effect of alcohol consumption is having on the quantity and quality of labor," 160 reported that they were not employing men who drank. There were only six of the 1,500 that thought the effect of alcohol was good. The idea had spread through the business world that alcohol was a handicap to business advancement and success and on this material basis alone it was being excluded from modern society. Facts of the kind referred to went to show that the turning down of alcohol was no reflection of a hysterical tendency, but rather a gradual spread of wholesome educational influence appealing to practical common sense. It was to be hoped that there had also been at work a more idealistic influence leading us to regard alcoholic indulgence as a mark of weakness—always to some extent a moral risk. Allowing for all statistical fallacies, it might safely be said that the evidence showing alcohol to be a social liability was consistently overwhelming and it was upon such evidence that any final decision must be made, cold-bloodedly and without feeling or prejudice.

Dr. OLIVER T. OSBORNE of New Haven expressed his enjoyment of the papers that had been presented and said that while there was nothing to be added to the scientific end of the discussion he wished to go on record as believing that the medical profession could get along without alcohol in the treatment of disease. That did not mean, however, that there were not indications which were not better met by alcohol than by some other drug. The main point in the discussion of alcohol and the law was the effect on well people. It was a question whether a little alcohol did any harm to a working man after he was through with his labors, but there was no question that alcohol taken in any amount by the individual deteriorated mental and physical work. He did not approve of legislation putting upon the medical profession and the druggists the onus of the distribution of alcohol; and therefore he and many others of the medical profession had taken no license to prescribe it. Many druggists also refused to be under suspicion in the handling of alcohol. It was a serious question as to whether the little alcohol a man might wish as a quieter of his nervous system and for its narcotic effects was not going to be succeeded by getting more active stimulants. There was no question but that the sale of coffee had increased fifty per cent. within the past year, and it was known that more drugs were taken. The harm of home brews and of miserably distilled preparations would soon be in evidence in the form of numerous digestive and nervous ailments. It could not yet be determined as to whether radical legislation was the best way in which to present this matter to the country, but he could not approve of the way it had been put upon us.

Dr. CHARLES E. DE M. SAJOUS of Philadelphia said that the paper he had submitted was in favor of the prohibition law, owing to the evil effects of the *abuse* of alcohol. But the Volstead Act was in itself an abuse —an abuse of power in that it imposed upon the public restrictions which were not warranted by scientific investigations which had shown that a three per cent. by volume beverage could not intoxicate. Law-abiding people, whether they approved of the amendment or not, were in entire accord with the proposition that public morality was not being promoted by keeping on the statute books laws which were creating outlaws on all sides. In most states the people were perilously near the situation of open evasion of the law and fresh technicalities were daily being invoked on both sides to defeat them. Events were increasingly proving that the perverse measures being adopted to enforce the 18th amendment were increasingly nullifying its benefits. In the papers read much had been said about efficiency. There was no doubt that alcohol reduced efficiency; but the point under discussion in the present connection was whether three per cent. beer, cider, etc., or the five per cent. wine taken after work by our Italian laborers, which promoted the hydrolysis of fatigue wastes, was going to do any harm, and whether the fact that we recommended this mild stimulation would not be of distinct benefit and help to eliminate much of the antagonism toward the law. There was no doubt that if the ugly side of the law were eliminated the good side with all its advantages could be preserved. The influence of the physicians in this matter should not be overlooked. That in nontoxic doses, alcohol promoted the defensive functions of the body had first been shown by Dr. Hare of Jefferson Medical College, and had been repeatedly confirmed in Europe. The profession could do much to preserve the beneficial effects of the 18th Amendment by allowing their opinions to be guided by the teachings of science and opposing the intemperate fanaticism of the Volstead law.

Dr. SPENCER L. DAWES of New York said that he had been very much impressed by what Dr. Fiske had said in a statistical way. Of course, anything could be proved by statistics, but he had been particularly interested in the statistical features regarding insanity in the State of New York, showing that it had decreased markedly. The question was, what was alcoholic insanity? There were other features which had to be considered beside alcohol. Dr. Dawes said that he had had to deal with all of these 41,000 insane in the State of New York. A man was reported as an habitual drinker—did he therefore have alcoholic insanity? Beside that, would it not have been possible to have had this decrease in alcoholic insanity with an elimination of the hard drinkers? Dr. Gregory talked about the great decrease of alcoholic cases in the psychopathic ward at Bellevue, but he did not say that the number of drug takers had quadrupled. How many of them came in every two or three months? One could not place a great amount of confidence in the statistics regarding the effects of alcohol on the insane in New York State. In the MEDICAL RECORD of May 7, 1921, the following paragraph appeared: "*Alcoholic Cases Increase in Kings County.*—An increase of nearly 120 per cent. in the number of the alcoholic cases in the Kings County Hospital within the last two months has been reported by Dr. Mortimer D. Jones, Medical Superintendent, to Bird S. Coler, Commissioner of the Department of Public Welfare. The report states that 650 persons were admitted to the alcoholic wards during the nine months ending April 1, against 299 for the corresponding period in 1919-1920. The cases have become much more acute in character."

Dr. JACOB DINER of New York said that he recalled very vividly a symposium on alcohol in the New York Academy of Medicine before the prohibition act had definitely gone into effect and was still under discussion. Dr. Gregory stated that he anticipated a marked increase in drug addiction as soon as the use of alcohol was prohibited. His prophecy was borne out by the figures mentioned by Dr. Dawes. Dr. Gregory had reversed himself now by reporting the number of reduced alcoholics, but he was careful not to mention the increased number of drug addicts. Dr. Diner said he believed that physicians would rather have a man committed to Bellevue for two to four weeks as an inebriate than to have to deal with a confirmed heroin or cocaine user. There was no question at all but that drug addiction had increased since the ostensible reduction of alcohol consumption.

Dr. REYNOLD WEBB WILCOX of New York said there was another phase of this matter which this Society as physicians should consider very carefully. Physicians were admitted by the state to the practice of medicine and required in their daily duties to obey three specifications: they should have the proper education, which the Regents of the state took care of; they should exercise due diligence, and they should exercise good judgment. The moment physicians were limited in the exercise of their professional judgment their usefulness as physicians would undoubtedly be diminished. Dr. Wilcox further said that he had not himself taken out a license to prescribe alcohol; there was no man up or down from the President big enough to make him a saloon keeper. He could conceive that the best educated man and the most conscientious man and the most moral man in the profession might believe that the exercise of good judgment demanded that a patient under certain circumstances should receive much more alcohol than was permitted under the Volstead act. It was easy to conceive a man, with all these great characteristics, feeling that there might be occasions in which the administration of other forms of alcohol was needed. The great moral wrong of this act was that it forbade men to exercise the good judgment which the law of the state demanded they should exercise. No moral question could ever be settled until it was settled right, and one was compelled to question the Volstead act and the arbitrary manner in which the regulations were carried out as well as the character of the men chosen to carry them out, men of criminal records who deliberately shot down their fellow men in cold blood without warrant of law. The definition of law was well stated in Professor Robinson's little book, that law was merely crystallized custom. That was all it was. We could not make people good by law, but we could make them bad. Dr. Wilcox said he was told by police magistrates and hospital authorities that men who were formerly satisfied with light wines and beer of which they were now deprived were turning to the saloons and drinking whiskey and other liquors of which there was a plentiful supply, thus perpetuating the worst form of intemperance. While he regarded the prohibition act as the greatest economic advance that had ever been made, he also considered that it was most severely to be criticised and condemned on moral grounds.

Dr. WILLIAM F. MILROY of Omaha said there were two points to which he wished to call attention in respect to this matter. The first was that probably the great majority of the members of the Society present resided in two or three of the great cities of the country and they should not form their conclusions in respect to this whole question simply from the observation of these few great cities. They must not forget the balance of the hundred million people living outside of these great cities, and the conditions among these people as influenced by this new law. He had heard of people in the State of Kansas, his eighboring State, who had grown up without ever seeing a saloon and some of them had never seen an intoxicated person. They had lived there since Kansas became prohibition state, and that was the condition in which they had lived to the present time and had lived for years. That suggested the other point, which was that not enough time had elapsed since the introduction of this law for any one to determine finally its ultimate value or consequences. The nation had lived drinking alcoholic liquors of various kinds throughout its history, and it could not be expected that in one, two, or even five years it would gracefully submit to the conditions imposed by this law. It was a matter that would take time, and if this present generation of drinkers saw fit to take themselves off by the illegal use of liquors it would leave the country in the future, if this law was carried out with its full intent, a very different country from what it had been in the past; the economic advantages would materialize and the disadvantages would disappear to a very great extent.

These two points ought to be recognized whatever might be one's attitude in respect to the physiological or therapeutic value of alcohol.

Dr. JACOB DINER of New York asked whether it was not a matter of fact and statistics that in many socalled prohibtion states there was a correspondingly greater consumption of alcoholic "patent" medicines.

Dr. MILROY replied that he could not answer definitely, but that the pure food laws of the country would take care of that question in the future as occasion would arise. It was well known that in the formulæ of many of these articles the allowance of alcohol had been cut off and restricted. In his own state of Nebraska prohibition had been in operation for about six years, and in his opinion the result had been most beneficial. In his own city with a population of over 200,000 the conditions had improved enormously. Of course it was true that liquor was sold—being imported from Canada and manufactured—but that was diminishing rapidly.

Dr. EUGENE L. FISKE of New York said he had tried to make clear in his paper that he drew no positive conclusions from the statistics with regard to the influence of prohibition, but he might have been misunderstood. He had stated that in 1920 the mortality in the industrial population was very low, but he had uttered a caution that no dogmatic conclusion should be drawn from the figures presented from Drs. Kirby and Pollock as regards the effect of prohibition. He made the point that long before prohibition there had been a steady decline in the use of alcohol due to other causes. He had stated that the admissions for drug psychoses had dropped from .38 to .28. He thought he had not read some figures relating to the proportion of users of alcohol in various groups investigated. It was generally considered that total abstainers formed a small minority of the population, that they were a peculiar group. The New England Mutual Life Insurance Company, through its investigations extending over 60 years, showed 38 per cent. of practically total abstainers. In two other companies, including one containing many Germans, the proportion was 64 per cent.; in another, 56 per cent.; in other industrial groups, 45 per cent.; commercial groups, 72 per cent.; and to these might be added a number who used alcohol casually but were not committed to its use. From what he had observed by intensive study of all the facts, he could see very good reason for figuring out a majority against alcohol, and it was erroneous to form the opinion that, because a great noise had been made, a group of agitators had put this thing over. Personally he had never engaged in anti-alcohol propaganda, but had collected facts and let them be used for what they were worth. He did not offer his paper as a brief for prohibition, but he did believe prohibition had been a wholesome thing. He believed that the forces of education and the practical common sense of the people were for a reduction in the use of alcohol before the law decreased consumption, and was inclined to agree with Dr. Kirby that there had been growing up a sentiment against alcohol and that political agitation had not had a great influence in the matter

Dr. JOHN C. HEMMETER, in closing, said that the blood of the human being normally contained under physiological conditions 3 1000 proportion of alcohol. The blood of several total abstainers examined, who lived largely on carbohydrates contained a slightly higher proportion of alcohol. The distillate of the human feces yielded a considerable percentage of alcohol, being largely from intestinal fermentation of carbohydrates and sugars, for the alcohol was made from the sugar; and as total abstainers were proverbially large consumers of sugar they distilled a little more alcohol than the consumer of alcohol, for the latter lived largely on a protein diet, from which no alcohol could be formed. It would be interesting to watch this situation, for the total abstiner would be the unconscious manufacturer of alcohol since he had the most favorable conditions for forming it. That little moonshine distillery was working all the time, and though the percentage of C_2H_5OH formed was small, yet it could only be estimated as having a pharmacologic effect because of continuous action; whereas the man who took his regular drink used it sporadically. Experiments on the isolated dog heart reported in the English *Journal of Physiology* eight years ago brought out the fact that when measured amounts of Ringer's solution mixed with different percents of alcohol were perfused through the heart and circulated through the coronary arteries, the blood oxidized the alcohol and those animal hearts performed a greater amount of work than the controls without alcohol. This was mentioned as being of biological interest at any rate.

Alcohol Is of Therapeutic Value.—Dr. LEWIS H. TAYLOR of Washington said that the Council of the American Therapeutic Society had instructed him to present to the society the following resolution: *Whereas* the use of ethyl alcohol and its preparations is not only justified but also indicated by observations made by laboratory investigators and clinical experience, therefore be it *Resolved* by the members of the American Therapeutic Society in convention assembled that alcohol has a proper place in the treatment of disease; and be it further *Resolved* that the least possible restrictions in the use of the drug compatible with the enforcement of the 18th Amendment be imposed on the members of the medical profession; and be it further *Resolved* that a copy of this resolution be sent to the proper authorities.

Dr OLIVER T. OSBORNE of New Haven said that he was not opposed to the resolution but at the same time he was not sure he wanted the American Therapeutic Society to go on with a rush. They should be deliberate in a resolution which was likely to be misunderstood and misinterpreted. He did not see that there was any way our methods of giving or not giving alcohol could be helped by the resolution. He did not wish to be on record as opposing the Volstead law if it was modified into a decent law. He did not approve of the law as it stood.

Dr. JACOB DINER said that Dr. Osborne was losing sight of the fact that the enforcement officers had the power to make whatever rulings they desired in order to stop the use of alcohol. That might lead and probably would lead to an entire upset of all pharmacopeial preparations. The prohibition officers had already promulgated certain changes in the U. S. Pharmacopœia preparations. Unless we took a definite stand and recognized the necessity of the use of alcohol in some form or another as a drug it might not be so very long before no tinctures or elixirs could be prepared, because they all contained alcohol. It might mean the abrogation of our privileges to prescribe a drug to meet certain conditions. This resolution was not in favor of antiprohibition but merely of the protection of the rights of the physician to use drugs as deemed necessary in the treatment of disease.

Dr. GEORGE H. HOXIE of Kansas City supported Dr. Osborne in his contention, for he believed that as medical men they would make a mistake if the society mixed in this fight. It seemed to him that the best attitude for medical men to pursue was the scientific one, keeping away from any discussions that would belittle them or tend to put them on a level with saloon keepers. He had himself refused to take out a license to prescribe alcoholic drinks. He agreed with Dr. Wilcox that the society should abstain from anything that might appear like coming down into the plane of the antiprohibition fight. He himself happened to have lived in Kansas, having been a member of the faculty of the State University for several years, and he could testify somewhat in answer to the question that had been put by Dr. Diner. He had found it a very delightful place to live in, and had found no difficulty whatever in prescribing whatever drugs he needed, and he did not believe the people of the state were to any extent damaged by prohibition. For the last few years he had lived in Missouri which had been wet until the Volstead act and could therefore contrast the wet with the dry neighborhood. If he had a choice of location witout knowing anything more about it than one was wet and the other dry, he would select the dry state. He did not believe the medical profession had been or would be interfered with in any legitimate way. If a protest as to the present condition of affairs was needed it should be made by those injured and not by the doctors. If the patients really did suffer their protests would reach Congress more effectively than if this society, a small group of medical men,

should enter such a protest. The majority of the men present were from the East and it would be wise for them to heed the warnings of Dr. Milroy and himself who represented another section of the country, and one that was vitally interested in the matter.

Dr. REYNOLD WEBB WILCOX of New York suggested that perhaps Dr. Osborne should bear in mind the fact that the trouble caused to physicians resulted not so much from the enforcement of the various acts of Congress and amendments to State laws—not from the laws themselves, as from the interpretations which had been put upon these laws, the rulings that had been made. In those cases that had had to be defended in court in order that the rights of human beings should be protected, it became necessary to point out to the court that the burden of proving that these rulings were germane to the law rested upon the district attorney, and that if they were germane to medicine and not to the practice of law they were rulings that the commissioners and the district attorneys would attempt to force at their peril. That was the law. He would dislike very much to have the society leave the matter as it stood at the present time, because if they should fail to act now the Associated Press would send out the news that the American Therapeutic Society declined to take action upon the value of alcohol as a therapeutic agent when that decision was to be based upon scientific grounds. That he would regard as very unfortunate. Personally he would like to see the very carefully drawn resolution passed upon by a large majority, and should it be so passed action by any other medical society would be entirely superfluous, because this organization, representing the best and most scientific knowledge as to the medicinal use of alcohol, would render a decision which could not be even questioned.

Dr. J. MADRIM TAYLOR of Philadelphia said he had heard a sudden resolution presented and was asked to vote for it; but he wished to make some pertinent response. This question could not be passed upon by this or any other body unless it contained a certain number of competent psychologists. It was the question of the effect of alcohol on the average individual. He did not believe this matter had been taken into proper consideration, and he objected. That was his stand.

The Society then voted upon the Resolution and it was adopted by a two-thirds majority.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO STATE BOARD OF MEDICAL EXAMINERS.

Denver, January 4, 1921.

(Continued from page 221.)

TOXICOLOGY.

1. Describe a case of poisoning by some mineral acid and caustic alkali. Give symptoms and treatment.
2. Describe opium poisoning. With what disease may it be confounded? Give differential symptoms.
3. Describe a case of poisoning by digitalis. Give symptoms and treatment.
4. Name chemical antidotes for the following poisons: Nitrate of silver, carbolic acid, lye, corrosive sublimate, sulphuric acid.
5. What are the dangers that may come from the use of salol in large quantities? Give symptoms and treatment.
6. What are the symptoms of iodism? Give treatment.
7. Describe the forms of ergot poisoning. Give treatment.
8. Describe the difference between physiological and chemical antidotes. Illustrate each.
9. How do corrosive poisons differ from true poisons? Give example of each. Describe symptoms and treatment.
10. Give symptoms and treatment for use of nitric acid poisoning.

In questions 1, 8 and 9 do not use poison asked for in other questions.

SYMPTOMATOLOGY.

1. Give the symptoms of variola and differentiate the eruption from that of varicella.
2. Discuss aortic insufficiency with regard to symptoms, physical findings, and etiology.
3. Discuss etiology, symptoms, and diagnosis of aneurysm of arch of aorta.
4. Give symptoms and physical signs in spontaneous pneumothorax.
5. Discuss the diagnosis and describe typical course of lobar pneumonia.
6. Discuss fully symptomatology and diagnosis of incipient pulmonary tuberculosis.
7. Discuss etiology, symptoms, and complications of vascular hypertension.
8. Discuss symptoms and physical findings in exudative pericarditis.
9. Discuss diabetes mellitus, symptomatology, pathology, and complications.
10. Give differential points between cerebral apoplexy, acute alcoholism, syncope, and postepileptic coma.

ANSWERS.

TOXICOLOGY.

1. POISON BY SULPHURIC ACID. *Symptoms:*—"When concentrated sulphuric acid is taken into the mouth, symptoms present themselves immediately. Its irritating action upon all the tissues with which it comes into contact is followed by severe burning and pain in the mouth, or extending down the throat into the stomach, and there is vomiting which occurs at once and consists of frothy material, shreds of mucus, liquid of a dark coffee-ground color, with more or less blood. Shreds of mucous membrane are found even in the first vomitus. The mouth is excoriated and its lining membrane is at first white, later changing to gray or brown. Salivation is marked. The injury to the lining of the mouth, throat, and esophagus is followed by considerable swelling and difficulty in breathing, the face usually taking on the livid expression of asphyxia. The material which is first vomited usually contains a large portion of the acid in a concentrated form, so that wherever it may touch the hands or clothing there will be found stains due to the action of the acid. The expression is anxious, the evidences of suffering and pain very great, the intellectual faculties clear, and death usually results suddenly at the end of eighteen to twenty-four hours after the poison is taken."

Treatment.—"When a strong acid has been taken, there is no substance which will have any material effect upon its action. The proper treatment would be an attempt at dilution and the administration of mild alkalies, such as cooking soda, chalk, or magnesia, with the usual soothing substances like barley-water, flaxseed tea, or oil. No tube should be introduced on account of the danger of perforating the already softened esophagus and stomach." (Dwight's *Toxicology.*)

POISONING BY CAUSTIC ALKALI. *Symptoms:*—"A nauseous acrid taste, rapid destruction of the mucous membranes and even the deeper tissues of the mouth and throat, burning pain in the throat and stomach extending very soon to the abdomen, which becomes exceedingly tender, aphonia, vomiting of bloody mucus, frothy and with a soapy taste, pulse small and thready, surface cold and covered with a clammy perspiration, great prostration, sometimes ending with convulsions, especially with children. When potassium hydroxide has been taken it sometimes shows its specific action on the heart, causing slow, weak pulse, the patient sinking into unconsciousness. Constipation is sometimes troubles me, but generally a bloody diarrhea supervenes. The urine is scanty and alkaline, or entirely suppressed. The blood is dark and gelatinous. If the patient survives a few days, sloughing of the fauces and esophagus may occur, followed by stricture and death from exhaustion or starvation, or the stomach may have been most severely affected and death result from destruction of its functions."

Treatment: Do not use stomach pump. The necessity for caution is here even greater than in poisoning

by the strong mineral acids, as the disorganized tissues are more rapidly softened. Give the weaker vegetable acids where accessible, as lemon juice, dilute vinegar, etc. In their absence the mineral acids may be given very dilute and cautiously, always remembering that too much of the antidote may be quite as injurious as the original poison. Vegetable or animal oils may also be given, as sweet oil, lard, butter, cream and milk. Where symptoms of heart depression appear, as slow, weak pulse and tendency to coma or convulsions, caffeine, digitalis or other heart stimulants may be given."—(Riley's *Toxicology.*)

2. The *symptoms of poisoning by opium* are as follows: "At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from forty-five minutes to fifty-six hours, usually in from twelve to eighteen hours. In cases of recovery after the stage of narcosis, the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting twenty-four to thirty-six hours."—(Witthaus' *Essentials of Chemistry and Toxicology.*)

Treatment of opium poisoning consists in washing out the stomach, preferably with a dilute solution of potassium permanganate; ambulatory treatment to keep the patient awake; artificial respiration is indicated, and strong coffee should be administered by the mouth or rectum; the bladder should be emptied by the catheter.

The following table (from Eisendrath's "Surgical Diagnosis") gives the differential diagnosis:

APOPLECTIC COMA.	UREMIC COMA	ALCOHOLIC COMA	OPIUM POISONING
Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supra-orbital pressure unless very profound.	Can be aroused unless very deep.
Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pin-point size.
Pulse full and slow, often arteriorsclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.
Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow—May be 6 to 8 per minute.
Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.	
Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.
Hemiplegia with convulsions on one side.			

3. *Symptoms of poisoning by digitalis:* "Nausea, and occasionally vomiting. Sometimes colic and diarrhea. After two or three hours, marked diminution in the frequency of the pulse, which may fall to 40 or even 25. Dyspnea, attended by a sense of oppression in the chest and coldness of the extremities. Headache, vertigo, and tendency to sleep. Usually attacks of syncope occur, provoked sometimes by the slightest movement of the patient. Death is generally by syncope, sometimes after several hours of coma succeeded by convulsions. *Treatment:* The patient must be kept strictly in the recumbent position. The stomach should be washed out with infusion of tea by the stomach tube. Stimulants should be given."—(Witthaus' *Essentials of Chemistry.*)

4. CHEMICAL ANTIDOTES. For *nitrate of silver*, sodium chloride. For *carbolic acid*, sodium sulphate. For *lye*, a very weak or dilute acid. For *corrosive sublimate*, milk or white of egg. For *sulphuric acid*, magnesium oxide or hydroxide.

5. *Salol*, in large quantities, may cause phenol poisoning.

Symptoms of carbolic acid poisoning: Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

The *treatment* consists in administering white of egg, sodium sulphate, or saccharated lime, followed by lavage. Alcohol is said to be antidotal. At one time alcohol was much used; just now the older remedies (such as sodium sulphate) are more relied on. Soluble sulphates form with carbolic acid the insoluble sulphocarbolates, which can be removed by lavage.

6. *Iodism* "is characterized by violent coryza, headache, a metallic taste in the mouth, increased salivary secretion, gastric irritation, and an acne rash. Elimination should be procured, the drug should be stopped, and pyrethrum root, tincture of belladonna, quinine, digitalis, etc., should be administered. The incorporation of tincture of belladonna (♏ 5) with each dose of iodide will generally prevent the disagreeable catarrhal symptoms."—*Pocket Cyclopedia.*

7. *Acute ergotism:* "In a large dose ergot acts as a gastrointestinal irritant, causing nausea and vomiting, gastralgia, colic, thirst, and purging. It slows the heart, raises the arterial tension greatly, dilates the pupils and produces pallor, vertigo and frontal headache. It stimulates the contraction of unstriped muscular fiber, especially affecting the sphincters and causing contraction of the sphincter of the bladder, making micturition difficult if not impossible. It produces cerebral and spinal anemia, a great fall of the body temperature, coldness of the surface, tetanic spasms, and violent convulsions." *Chronic ergotism* "occurs in two forms, the convulsive and the gangrenous—either usually excluding the other. The convulsions are tetanoid spasms of the flexor muscles, the uterus, the intestinal fibers, and the muscles of respiration, ending in coma and death by asphyxia. The gangrenous form begins with coldness and numbness of the limbs, formication of the skin all over the body, loss of sensibility and abolishment of the special senses, bullæ of blood and ichor, followed by dry or moist gangrene of the lower extremities, buttocks, and other parts, epileptiform, convulsions, coma, and death. Autopsies show changes in the posterior columns of the cord, resulting probably from spinal anemia."—(Potter's *Materia Medica*, etc.)

Treatment: Wash out the stomach; give castor oil or magnesium sulphate; keep the patient warm, and at rest; stimulate with alcohol, or nitroglycerin, or strychnine, or caffeine.

8. *Physiological antidotes* act as such by combating one or more of the physiological actions of the poison, such as opium for belladonna.

Chemical antidotes act as such by uniting chemically with the poison and thus converting it into a harmless or insoluble compound, such as magnesium sulphate for lead poisoning.

9. A *poison* is a substance which, on being in solution in or acting chemically upon the blood, causes death or serious bodily harm.

A *corrosive* is a substance capable of producing death or injury by its chemical action upon a tissue with which it comes in contact. Corrosives and poisons also differ in other respects. Corrosives act upon dead and living tissue alike, while poisons, as a rule, do not. The violence of corrosion is directly proportionate to the degree of concentration, while the action of poisons depends upon the actual quantity absorbed, but in no wise on the degree of concentration of the solution taken. A corrosive may kill by destroying the skin, producing an injury resembling a burn; the poisons, if applied to the skin, act only when absorbed.

Example of a poison, aconite; *of a corrosive,* hydrochloric acid.

ACONITE. "*The symptoms of poisoning by aconite* usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling, first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock if a large dose of the alkaloid be taken, but more usually it is by syncope.

"The *treatment* should be directed to the removal of the unabsorbed poison by the stomach tube, and washing out of the stomach with infusion of tea holding powdered charcoal in suspension. Stimulants should be freely administered"—(Witthaus' *Essentials of Chemistry.*)

HYDROCHLORIC ACID. "The symptoms produced are similar but less in severity than those due to other acids. Dark clothing is stained at first a bright red, changing to a reddish grown. Mucous membranes are stained white or grayish, and a false membrane is sometimes formed in the fauces. The shortest period within which fatal results have followed its taking is said to be two hours, the average perhaps being eighteen to twenty-four, and death has resulted from the taking of something less than a half ounce.

Treatment. Treatment is similar to that of poisoning by sulphuric or nitric acid."—(Dwight's *Toxicology*).

And see Questions 1 and 10.

10. NITRIC ACID. *Symptoms:* Sudden and acute burning pain in epigastrium and extending from mouth to stomach; violent and distressing vomiting of acid and dark material. Eschars where the acid has come in contact with skin, lips or tongue; these are first white, then yellow or brown.

Treatment: Magnesia suspended in water, or a strong solution of soap. Do *not* use the stomach tube.

SYMPTOMATOLOGY.

1. *Symptoms of variola:* "After twelve days' incubation, the malaise of onset comes on. Its most notable features are—shivering, frontal headache, pains in the back, vomiting. In children there may be convulsions. The temperature runs up rapidly, with all the phenomena of 'fever.' On the third day the fever usually declines and the rash appears as a papule. Soon, however, the symptoms become worse and more pronounced than before, the fever increases, and on the ninth day, when the rash becomes pustular, the so-called secondary or suppurative fever is fully developed, and assumes a septic type with oscillatory temperatures. There may be severe rigors and a rapid assumption of the typhoid state. There is great swelling of the face—the eyes may be even closed up—and too frequently the patient dies; or the fever may subside, and the scabs commence to dry, falling off finally on the eighteenth to twentieth day, and leaving a more or less pitted appearance."—(Wheeter and Jack's *Handbook of Medicine.*)

(1) Very young children are attacked with varicella, whereas variola usually shows itself in adults. (2) Vaccinated children readily take varicella; not so variola, even in the modified form. (3) Children who have had varicella may contract variola, even soon afterwards; or the two diseases may coexist. (4) Varicella is noninoculable, whereas variola is notoriously so. (5) The eruption of varicella appears in 24 hours; that of variola not till the third day. (6) The febrile symptoms continue after the eruption appears in varicella; those of variola subside. (7) In varicella the spots come out in excessive crops; this is never seen in variola. (8) The spots in varicella are unilocular, and collapse on being punctured; the spots in variola are multilocular, and do not collapse on being punctured. (9) In varicella the eruption is very irregular, and appears over the body generally; in variola it appears in groups of threes and fives, and is always seen on the limbs. (10) The papule in varicella is soft, and disappears on stretching the skin; in variola it is hard and shotty, and does not disappear on stretching the skin.—(From J. W. Moore's work on *Variola and Varicella.*)

2. AORTIC REGURGITATION. *Symptoms:* "So long as the cardiac hypertrophy is just sufficient to compensate for the valvular condition, there are no symptoms, but as the muscle walls continue to increase symptoms of cardiac hypertrophy present themselves, such as forcible cardiac action, with marked pulsation of all the vessels including the capillaries, the characteristic forcible and receding pulse ('water-hammer pulse' or 'Corrigan pulse'), head ache, insomnia, tinnitus aurium, congestion of the eyes and face, etc. Precordial pain is usually present in aortic disease. It may be a sensation of constriction in the cardiac region or it may consist of sharp, shooting pains extending to the arms —anginoid attacks. As soon as the slightest failure of compensation occurs, the cardiac action becomes excessive and distressing. Palpitation is present and causes anxiety and fear on the part of the patient. When there is complete rupture of compensation, there develop, either gradually or rapidly, dyspnea, increased on exertion, cough, cyanosis, hepatic enlargement, renal congestion with scanty, albuminous urine, ascites, and dropsy. If mitral insufficiency is now superadded, general venous stasis and death rapidly follow. Sudden death is most frequent in this form of valvular heart disease."

PHYSICAL SIGNS. "*Inspection* shows that the cardiac impulse is forcible and displaced downward and to the left. The pulsation is visible far beyond the normal apex.

Palpation confirms inspection. It may at times serve to detect a diastolic thrill over the base of the heart and the adjacent large vessels. The Corrigan pulse and the capillary pulse are recognized by palpation.

Percussion serves to demonstrate an increase in the area of cardiac dullness downward and to the left. Occasionally it is increased upward and to the left of the sternum as the result of hypertrophy of the left auricle.

Auscultation reveals characteristic alterations in the heart sounds. The first sound is forcible; the second sound is replaced or associated with a churning, rushing, or blowing murmur of low pitch, well heard at the second right costal cartilage (aortic area) but most distinct at the junction of the sternum and the fourth left costal cartilage. It is diastolic in time and is transmitted downward and toward the apex. A presystolic rumbling murmur (*Flint murmur*) may occasionally be heard over a limited area at the apex."—(Hughes' *Practice of Medicine.*)

Etiology: Generally, it is the result of an acute endocarditis following rheumatism or an acute infectious disease; but it may be due to alcoholism, syphilis, gout, arteriosclerosis, chronic nephritis, or excessive muscular labor.

3. ANEURYSM OF ARCH OF AORTA. *Etiology:* "There are many reasons why aneurysms should be so common in the arch of the aorta: (1) It is much curved; (2) the first part of the arch has very little support; (3) the blood stream ejected during systole of the heart tends to bulge the aorta locally; (4) this part is much more affected by the variation of the cardiac pressure than the distal arteries; (5) it gives off large branches in a very small area; (6) the vessels tend to dilate during inspiration; (7) aortitis and atheroma are

very common in this situation. Aortic aneurysm occurs most frequently among men who are either prematurely old through intemperance, syphilis, etc., or in those engaged in occupation which tend to increase the normal aortic strain, such as hammermen, brewers, young soldiers.

Symptoms "depend on the portion of the arch affected, and on the size and shape of the aneurysm:

1. *Symptoms in connection with the Circulation.*—"Palpitation, anginoid pains, imperfect filling of the arteries, and sometimes difference in the two radial pulses.

2. *Symptoms due to Pressure*—"(1) There is difficulty in swallowing, especially solids. (2) Less air enters the lung of which the bronchus is pressed upon, and the breath sounds are consequently weak. There is much dyspnea, attacks of the so-called aneurysmal asthma, or a peculiar alteration of the voice and cough. Hæmoptysis may occur later. (3) *Implication of Nerves.* The symptoms will depend on the amount of pressure exerted on the nerves. Thus, if *slight*, we get symptoms due to *irritation;* if *severe*, symptoms due to *paralysis*. The nerves most likely to be involved are

	IRRITATION	PARALYSIS.
Left Recurrent Laryngeal	Alteration of voice; and stridor, due to spasm.	Aphonia. Paralysis of left vocal cord.
Phrenic	Painful and persistent hiccough.	Intercostal breathing. Death.
Sympathetic	Dilatation of the pupils. Pallor from constriction of the vessels on the one side. Rapid action of the heart.	Contraction of the pupil and flushing of that side of the face.
Vagus.....	Depressed action of the heart. Vomiting and nausea.	Irregular action of the heart. Pneumonia. Death.

(4) Edema of the superior extremities, one side of the head, etc. (5) Rapid emaciation, and fatty stools. (6) *Bones.* Erosion and absorption; the process being accompanied usually with intense boring pain."—(From Wheeler and Jack's *Handbook of Medicine.*)

Diagnosis: "The presence of a tumor, as shown by the abnormal area of dullness, with expansile pulsation and a bruit in the region occupied by the aortic arch, is diagnostic. The *x*-ray will serve to define its exact situation and outlines. The signs and symptoms will vary according to the part of the arch involved."—(Hughes' *Practice of Medicine.*)

4. PNEUMOTHORAX. *Symptoms:* "The onset is abrupt with sudden or sharp pain in the side, intense dyspnea, symptoms of collapse, coldness of the surface, and cold sweats. These symptoms in many instances follow a severe or violent paroxysm of coughing. In severe cases the acute pain and distressing dyspnea are constant until death.

Physical signs: "Inspection serves to detect enlargement of the affected side with absent or diminished respiratory movements. The intercostal spaces are widened and sometimes bulged out so that the surface of the chest is smooth. The apex beat is displaced. *Palpation* reveals diminished tactile fremitus. *Percussion* yields marked changes in the resonance. Immediately after the rupture, the percussion-note is hyper-resonant, or even tympanitic or amphoric in quality. If the amount of air in the pleural cavity becomes extreme, there is dullness on percussion, associated with a feeling of great resistance or density. When effusion of blood occurs, dullness is obtained over the lower part of the chest, hyper-resonant, or tympanitic percussion-note over the upper portion of the chest, these sounds changing as the patient changes position. *Auscultation* demonstrates several characteristic features. The normal vesicular murmur may be diminished or absent. The typical amphoric respiratory sound is heard when the fistula is open, usually associated with a metallic echo. The vocal resonance may be diminished or absent, or, rarely it may be exaggerated, with a distinct metallic echo, *Metallic tinkling*, or the bell sound, is sometimes distinctly produced by breathing, coughing, or speaking, after the development of inflammation of the pleura. After the development of pleuritis, suddenly shaking the patient gives rise to a splashing sensation, the succussion sound, if both air and fluid are present in the pleural cavity."—(Hughes' *Practice of Medicine.*)

5. *Diagnosis of lobar pneumonia* is based on the physical signs and symptoms. "*The first stage* is characterized by sudden onset with chill a sharp pain in the side, rise of temperature, a short and sharp cough, rusty-colored, viscid sputum, and dyspnea. There may be headache, scanty urine, insomnia, and herpetic vesicles on the face, and there is always an increase in the number of leucocytes in the blood. Physical examination will reveal diminished expansion, impairment of the normal percussion note, feeble or suppressed respiratory murmur, moist or dry râles, crepitation, and sometimes a pleural friction sound.

"*In the second stage* the dyspnea is more marked; the face is more or less livid in color; the temperature is high (104°-105° F.); and the pulse increases in rate (110-120), its tension and fullness lessening with the progress of the disease, and growing feeble and intermittent. Headache, delirium, and various other nervous symptoms may be present. Expansion is diminished and vocal fremitus is exaggerated upon the affected side. There is dullness with increased resistance over the consolidated lung, and auscultation detects bronchophony or bronchial breathing over this same area.

"*The third stage* is ushered in by a sudden drop of temperature on or about the fifth or ninth day, followed by a natural sleep, free sweating and relief from suffering. In this stage the crepitant râle (râle redux) is heard in the midst of the bronchial breathing, together with numerous moist râles. Dullness may persist for some time, but usually by the twelfth or fourteenth day the lung has returned to its normal state."—(Gould's and Pyle's *Pocket Cyclopedia.*)

In a *typical case of croupous pneumonia*, "there may be slight catarrhal symptoms for a day or two; but as a rule the disease sets in abruptly with a severe chill, which lasts from fifteen to thirty minutes or longer. In no acute disease is the initial chill so constant or so severe. The patient may be taken abruptly in the midst of his work, or may awaken out of a sound sleep in a rigor. The temperature taken during the chill shows that the fever has already begun. If seen shortly after the onset, the patient has usually features of an acute fever, and complains of headache and general pains. Within a few hours there is pain in the side, often of an agonizing character; a short, dry, painful cough begins, and the respirations are increased in frequency. When seen on the second or third day, the picture in typical pneumonia is more distinctive than that presented by any other acute disease. The patient lies flat in bed, often on the affected side; the face is flushed, particularly one or both cheeks; the breathing is hurried, accompanied often with a short expiratory grunt; the alæ nasi dilate with each inspiration; herpes is usually present on the lips or nose; the eyes are bright, the expression is anxious, and there is a frequent short cough which makes the patient wince and hold his side. The expectoration is blood-tinged and extremely tenacious. The temperature may be 104° or 105° F. The pulse is full and bounding and the pulse-respiration ratio much disturbed. Examination of the lungs shows the physical signs of consolidation—blowing breathing and fine râles. After persisting for from seven to ten days the crisis occurs, and with a fall in the temperature the patient passes from the condition of extreme distress and anxiety to one of comparative comfort."—(From Osler's *Practice.*)

6. In *incipient pulmonary tuberculosis*, "there is no expectoration, and probably no hemoptysis, but a persistent dry, hacking cough, possibly with a slight afternoon rise in temperature and occasional feverish attacks ascribed to colds or influenza; there is slight loss in body weight, and the general health is suffering. The physical signs are mainly defective entry of air

into one lung, probably at the apex; slight prolongation of expiration, possibly cogwheel respiration, perhaps impaired movement of the chest on one side, and it may be very slight dullness if the deposit be near the surface. Rapid breathing and a persistently frequent pulse are suggestive of early tubercle. The injection of tuberculin giving pyrexia may be tried as a diagnostic reaction. The *x*-rays, using the screen, may quite early show a lagging of the diaphragm on the affected side."

7. VASCULAR HYPERTENSION. *Etiology:* Chronic infections; syphilis, typhoid; streptococcic focal infections (from teeth, tonsils, nasal sinuses ears, appendix, genital organs); chronic intoxication; alcohol, tobacco, lead; intestinal putrefaction; chronic nephritis; hyperthyroidism. *Symptoms:* Nervous irritability, slight indigestion, nervousness, palpitation of the heart, insomnia; headache, shortness of breath on slight exertion, anginoid attacks, amnesia; later, dyspnea, thoracic oppression, apoplectiform or epileptiform attacks, intermittent claudication, retinal hemorrhage.

Complications: Cerebral hemorrhage, chronic nephritis, myocarditis, angina pectoris.

8. ACUTE EXUDATIVE PERICARDITIS *Symptoms.*—Subjective symptoms are often lacking and only a routine examination of the heart enables its recognition. There may be vague precordial discomfort or constriction, or pain. It is felt over the pericardium, occasionally extending to the left arm; or at the ensiform cartilage and over the upper abdomen. It is seldom increased by pressure. There may be dyspnea, palpitation, and perhaps a weak and irregular pulse. Fever, (rarely exceeding 102° to 102.5°), is present. The *physical signs* are friction rub, which usually begins at the base of the heart and extends more or less over the surface. Sometimes this friction may be observed by the palpating hand. It is not synchronous with the cardiac sounds, and may intermit.

9. DIABETES MELLITUS. The *symptoms* are: Weakness, excessive thirst, frequent urination, and increase in the amount of urine voided, the presence of glucose in the urine. Hyperglycemia is a feature of the disease; pruritus, emaciation, a dry and harsh skin, lost or diminished knee-jerks, coma, and air hunger are often present. The urine also contains acetone, oxybutyric acid, and diacetic acid, sometimes albumin and casts, and an increased output of nitrogen.

Pathology.—"The theoretic interpretation of diabetes varies with the view which may happen to be held of the glycogenic function of the liver. Normally about 0.1 per cent. of sugar is present in the blood, and a minute trace, which the clinical tests cannot detect, in the urine. When the amount in the blood is more than 0.2 per cent. an appreciable glycosuria occurs, and even in health a temporary glycosuria may be produced by an ingestion of sugar beyond the physiological limit. The appearance of sugar in the urine is thus due to an excess of sugar in the blood. The usual view of the glycogenic function is that the liver converts the carbohydrates brought to it from the intestines into glycogen, which it stores up as a reserve, and gradually reconverts into sugar and delivers *via* the blood to the tissues according to their needs. On this view the excess of sugar in the blood is due either to excessive production of sugar in the liver, or to diminished oxidation by the tissues. On the other hand, Pavy holds that part of the ingested carbohydrates is converted by the intestinal villi into fat, and another part is synthetically built up into proteids, in which forms it reaches the blood, and that only a portion reaches the liver, where it is stored up as glycogen, and prevented from entering the general circulation except in synthetic combination with proteid bodies. A temporary glycosuria would therefore be due to a defect in the sugar-transforming mechanism, and diabetes to its arrest, permitting the passage of unaltered glucose. In mild forms of the disease, a diet free from carbohydrates stops the glycosuria, the excess of sugar being thus derived from the carbohydrates of the food; but in severer cases, glycosuria persists though carbohydrates are withheld, and sometimes even though no food is taken. In these instances, sugar is formed by disintegration of the proteids of the food, and in the gravest cases by disintegration of the body proteids. It remains to explain why the excess of sugar is not utilized by the tissues, is not, that is, oxidized in the ordinary manner by the muscles. It has been conjectured that it may require previous elaboration in other organs, and as the pancreas is in many instances diseased attention has been directed to that gland. The recent researches of the younger Conheim are suggestive in this regard. He finds that neither pancreatic juice nor muscle juice has singly any action upon sugar, but that when the two are combined the sugar is rapidly broken up. He holds, therefore, that the proenzyme produced in the muscles is only activated by a glycolytic substance contained in the pancreatic juice, and probably derived from the internal secretion of the islands of Langerhans. Extensive disease of the pancreas would destroy this substance, and render the sugar unavailable for combustion in the muscles. It must be added that, in some cases, no disease of the pancreas or liver has been found. In some of these there has been disease in the region of the 'diabetic puncture' (floor of the fourth ventricle)."—(Wheeler and Jack's *Handbook of Medicine.*)

Complications are: Pruritus, eczema, boils, cataract, retinitis, neuritis, albuminuria, cirrhosis of kidney, acidosis, and tabes.

10. *Coma from Apoplexy.*—"The coma is usually profound, and the patient can not be aroused. The face is flushed or pale and cyanotic. The respirations are slow, stertorous, and sometimes of the Cheyne-Stokes type. The lips are blown out, and one cheek flaps more than the other during respiration. The pulse, as a rule, is full, strong, and infrequent, and the arteries are hard. The pupils do not react to light, are dilated, and often unequal. There may be conjugate deviation of the head and eyes—i.e., they are turned persistently to one side. One side of the face is usually paralyzed, as indicated by the smoothing out of its wrinkles, the flapping cheek, and the droop of one angle of the mouth. By lifting the limbs and finding those of one side to fall more flaccidly than those of the other side, the presence of hemiplegia may be demonstrated. The skin is dry and the temperature of the body above the normal.

Alcoholic Coma.—"It may or may not be possible to arouse the patient. If he can be awakened, he may protest by words or blows. The face is usually flushed, often somewhat cyanotic, more rarely pallid. The respirations are of normal frequency, deep, and sometimes stertorous. The odor of alcoholic liquor can be detected in the breath; and there is usually the peculiar sour, mawkish smell which results from the disturbing effect of alcohol upon the buccal and gastric mucosa—the odor of "drunkard's stomach." This odor is of no value as a diagnostic symptom; its absence is of importance as a negation of alcoholism. The pulse is rather rapid, full and strong, finally becoming small and feeble. The pupils are equal, and either of normal size or dilated. Very commonly the skin is cool and moist, and the bodily temperature below the normal point. Convulsions are infrequent, but there may be some local muscular spasm or twitching.

Syncope.—"Unconsciousness from sudden anemia of the brain is rarely confounded with other forms of coma. The pallor of the face is absolute, the respirations are shallow and almost imperceptible, the pulse is weak, perhaps absent, and the pupils are widely dilated. The eyes may remain open. If the syncope is due, as it is in the majority of cases, to a temporary weakness of the heart action from emotional causes or the sudden assumption of the erect position by an enfeebled person, consciousness will soon return under appropriate treatment.

In *coma from epilepsy*, "the history of the convulsion, the bitten tongue, the foam on the lips, and, above all, the brief duration of the gradually lessening unconsciousness, are in the majority of cases sufficient to settle the question. The face is congested, the breathing stertorous, the limbs are relaxed, but there is no hemiplegia."—(From Butler's *Diagnostics of Internal Medicine.*)

(To be continued.)

Sympathectomy for Raynaud's Disease.—Mauclaire cites a case of this intervention in the practice of Dr. Ramondi. The immediate result was brilliant, but there was a recurrence in five months.

Miscellany.

NEW BOOKS AND OLD.

XI. THE MEDICAL LIBRARY.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

DR. OSLER used to say: "To study the phenomena of disease without books is to sail an uncharted sea, while to read books without patients is not to go to sea at all." Books then are the charts of medicine. There is to me no more fascinating study than comparing the charts of the early mariners with those of today and of yesterday. By so doing we can trace the history of the world, the rise and fall of empire, the voyages of discovery and of conquest. Gradually the outlines of the coasts become more accurately charted, but the constant change requires from time to time corrected charts, for currents deviate and coast lines vary so that no matter how true a map it was a hundred years ago, the mariner of today wants the present day chart when he sails out for some distant port. But the charts, the maps, show not only the configuration of the land but the artificial boundaries of nations, with the constant change, the eternal human ebb and flow, never to be fixed until the end of man. In medicine, countless mariners course up and down the broad highways of the sea searching for the promontories of truth. Little by little we have acquired a reasonably accurate chart of a fairly wide domain. We know the outline of much of the coast, the higher hills and mountains, some of which brave and undaunted souls have climbed, whilst others have sailed far up the broader rivers. Like the earth, the territory of medical truth has been and is occupied by a restless, uncertain people, and the scars of many wars and conflicts have left their unmistakable traces. The medical books are the maps of these countries by which we can follow the early adventurers. Some have sailed for commerce and some for discovery and some for mere adventure, and many are the strange trophies and stranger tales the travelers bring home. The domains of medical knowledge have been ruled and dominated by many great minds and schools. These kings and nations of the intellect have arisen, made converts, ruled and fought and vanished by hundreds and thousands, leaving, as a rule, no imprint; but there are some who charted the domain as they found it, or thought that it was, and today we can look back and, in part, say with Browning:

> "This rage was right in the main,
> This acquiescence vain."

The Medical Library is a school, a very important school, where one may commune with all the old medical worthies for the asking. What a furore it would create if it were announced that Laennec, or John Hunter, or William Harvey, or any other of the great men of the profession, would be present at our meeting. How the hall would be crowded! How eager each to hear what the great man had to say! And yet how unmindful are most of us of the fact that the best that Laennec, that John Hunter or William Harvey did and said are with us constantly, on the shelves of our Library. Any day we may wander at will with Louis through the wards of the Hôtel Dieu and listen to the wonderful descriptions of typhoid fever, or with Trousseau through the Hôpital St. Antoine, or again at the Hôtel Dieu and learn at first hand how to tell infantile tetany or gastric vertigo—to mention only two of the things to which his name is forever linked. Would you walk five miles to hear Hippocrates read his writings on malaria or his crisp description of mumps? Of course you would, or travel half the continent over; but how painfully few take the trouble to listen to the greatest of all medical teachers. Have you imagination? With the aid of a few volumes you may travel to the temples of Æsculapius at Cos or at Pergamos, where, on some wooded mountain side, trained priests will show you how the old Greek ministered to the sick, and find that it is not a far cry from there to the modern mineral spring or some of the places where they heal by faith, prayer, and ritual. You can slip easily across to Rome and listen to Celsus on surgery, or if you are interested stop to hear Soranus of Ephesus on midwifery or obstetrics, or the diseases of children, or call on Aretæus the Cappadocian and at first hand get descriptions of pneumonia, elephantiasis, tetanus, or diphtheria. He would tell you that he was the first to differentiate cerebral from spinal paralysis and to describe the decussation of the pyramids. As on a magic carpet one at will can visit Iba Sina the "Prince of Physicians," commonly called Avicenna, or listen five minutes to the Ladies of Salerno, or slip into Montpellier to be charmed by the alchemists, or as far as Basel to see Paracelsus burn the books of Galen and Avicenna. Endless the journey, and we may choose at will the great souls who have labored and left their best for our delectation. And we close the book and we are at home again.

The Library is not only a place where are garnered the best work of the masters of the times that are gone, but it holds equally as well the best thought of the present age. In the new books, and particularly in the monographs and journals, one finds an ever changing store of information: what the best men are doing the world over for all the different diseases and conditions. Woe unto the man who fails in his duty of keeping up with the times! Only too often are his sins of omission visited upon the heads of his patients. Sometimes, indeed, they may descend upon his own as in the case related by Sir William Osler of the physician who brought his cretin son for diagnosis. For years the misshapen, grotesque dwarf sat directly under his father's eyes, and for years the journals and later books had featured the results obtained by the use of desiccated thyroid and had pictured the cretin with its unmistakable appearance. Both passed unnoticed, and when asked why he had not recognized the condition himself the poor father answered that he was too busy practising medicine to read books about it. The lesson is obvious.

Unless one takes advantage of the best modern thought much is missed. Take for example the hypertrophic stenosis of the pylorus—that terrible condition first clearly described by Hezekiah Beardsley of Connecticut, in 1788, and which formerly largely claimed its victims. Unless one reads the books it might escape diagnosis, or if

it did not, might have the rather unsatisfactory operation of gastroenterostomy suggested as a cure. If the surgeon or pediatrist was up to date of course he would suggest the simpler and far safer operation of Rammstedt, or, perhaps even better, that suggested by Strauss of Chicago, and but recently described, and who knows but that some far better method of treatment may be forthcoming tomorrow. Only by continuous and persistent reading of journals and the use of the Library can the physician know the latest and best.

We can only give the profession the opportunity to use the splendid collections of books at their disposal. We cannot drive them to the Pierian spring, much less make them drink and drink deeply of it; but those of us who have labored in the interest of the Library, and of medical libraries in general, at least have the great satisfaction of knowing that we have paved the way for the profession, and if they persist in straying in the bypaths, instead of on the broad highway of knowledge, we can only point again and again at the sign board with the finger pointed to *success*. For it means success to be well informed. Look about at the most successful medical men, successful in the real sense of the word, and you at once see that they are successful because they know.

The users of libraries are an interesting lot, and the most indefatigable are book worms and the authors. The latter raise the number of loans and readers tremendously. An old truth, as Boswell reports Dr. Johnson saying: "A man will turn over half a library to make one book." It is indeed these readers, who are also writers, that esteem books at their true worth, as Sir William Osler has phrased it: "Only a maker of books can appreciate the labors of others at their true value." These readers are, as a rule, trained and know how to find what they want, but the average reader needs help which only the specially trained librarian can give. Without such help he is like a visitor in an unlabeled art gallery without a catalogue. To quote Dr. Johnson again, "Knowledge is of two kinds. We know a subject ourselves or we know where we can find information about it." Now almost any doctor knows that medical information can be found in a medical library, but there are but few men who really know how to go about extracting it.

And here it is that the trained worker comes in. Thanks to the Library Schools and the American Library Association it is now possible for library workers to learn the essentials under competent supervision. The special medical training comes only by working in the medical library. The trained worker should know where to find information of all kinds, and so save the time and energy of the reader who does not know. With books in book stacks, and only a card catalogue, many become discouraged and give up the task of seeking knowledge on some important topic because they do not know how to go about it.

It has been a dream of mine, for a long time, to have a special course of a week or two at some large library where the medical librarians could teach each other, and be taught by special instructors, in how best to use the library and how to help others. However useful collections of medical books are it does not seem that they fulfill, as yet, their highest function.

There was a time when libraries were largely presided over by chauvinistic book lovers, as jealous of their charges as an anxious lover. Their happiest days were those in which there were the fewest readers to disturb them. There is the well known story of one of the former librarians at Harvard, who was seen one day at closing time with a smile of satisfaction on his face. On being asked why he was so happy he replied that every book except two was standing in its place on the shelves, and that Agassiz had the missing ones and he was going over to his house to bring the vagrant volumes home.

Happily this attitude has passed, or is rapidly passing, and the modern medical librarian counts his happiest days those in which the greatest number of volumes have been consulted and loaned.

The modern medical librarian should be well trained in general library work, and of necessity familiar with the latest and best in cataloging and on the other technical features of the work. The monumental labor of Billings, of Fletcher and others in the Index Catalogue of the Surgeon General's Library and in the Index Medicus, now so ably carried on by Garrison, have lightened the labors of the medical librarian. Given these two aids, time and assiduity, one can bring together the literature of any given subject. The ideal librarian should be able to do more. He should be able to help the busy practitioner who wants a few authoritative articles on some subject together with the latest expression of opinion. With comparatively little aid from specialists in various lines, it should be possible to keep listed on catalogue cards the most important contributions on the subjects most liable to be inquired about; and a small medical library society, or committee composed of two or three members of each specialty, by meeting once a month for an hour could keep the matter well in hand to their own satisfaction, and that of everyone else. With an authoritative leader this altruistic work could be carried out. And what a comfort and help it would be to be able to get at a moment's notice the latest and the best without wasting time and without tiresome search. There are not so many record breaking contributions, nor so many with really good bibliographies, so that the catalogue, while large, would not be formidable. The size could be kept down by deleting older articles in favor of better or more recent ones.

Library Committees have to pick and choose carefully, and in the great stream of books that comes ceaselessly from the presses only the most useful can be chosen. Billings, in his address entitled "Our Medical Literature," says:

> There will be a certain number of medical books and papers printed next year, just as there will be a certain number of children born; so we can within certain limits predict the number of these births and the proportion of the sexes, or even of monsters; so we can within certain limits predict the amount and character of literature that is to come, the ideas that are yet unborn.

This plethora of printing renders the choice exceedingly difficult when the number of purchases is limited—the difficulty being greater than ever before.

The modern medical literature is more fantastic than that of the past. The field for the imaginations is so much larger, and cheap printing has led fools to write that should otherwise have remained silent. It is impossible to sift all the good from the bad, they are so intermingled, and yet one skilled in interpretation can sort with reasonable accuracy the useful from the useless. Through years of review work one comes to regard much of the modern medical press as not unlike the stream of garbage that some cities pass on endless belts before trained pickers. Here and there a precious gem, a bit of gold or silver, a countless lot of used and tattered truth from other days, useful but not new, and then a vast amount of by-products, ashes and refuse that weary, even if the amount astonishes the beholder. Fortunately for the reader, there are certain sources where the output is not refuse, but the produce of honest toil, and these books and journals are like the output of the workshop, some better than others, but for the most part honest and well intentioned. But even here one must test the wares carefully before he chooses, for there are skillful imitations, and pails that will not hold water, and cracked pots, and perhaps the task is more difficult than with the garbage. But Time, who tests all things, always tells and, in the end, the real is separated from the false.

One should not be too hasty in deciding what is of lasting value and what is of mere ephemeral interest. As Oliver Wendell Holmes remarked: "There comes a time for every book in the library when it is wanted by somebody." Hundreds of examples could be cited of books which have become classics and yet were spurned even by second hand book dealers. Semmelweis' Essay on the Contagiousness of Puerperal Fever once went a-begging at a shilling a copy and a dozen copies of Beaumont's Plattsburgh edition of his researches on the Physiology of Digestion mouldered on the shelves of our own Baltimore book shops until an essay of Dr. Osler's brought the volume to local attention, when a dollar sufficed to claim a copy. Osler, himself, once told how he picked up Auenbrugger's *Inventum Novum*, in Italy, for a lira.

The Medical Libraries of this country have for the most part not received the financial support that their importance to the community would seem to warrant. For bricks and mortar money is always forthcoming, but not so freely does it come for books and journals, which recalls Mr. Dooley's remark that libraries do not concern books but architecture. If one would write his name in more than water, a special fund in a library with its bookplate or inscription furnishes a means of keeping it before the coming generations, perhaps the surest way. The Libraries of the New York Academy of Medicine and the College of Physicians of Philadelphia, have inscribed the names of their munificent patrons and donors on tablets of marble inside the doorway. How many would know about Sir Thomas Bodley were it not for the Bodleian Library, or of John Radcliffe were it not for the Radcliffe Library? One pauses to wonder whether Mr. Carnegie will not be known for centuries hence as a founder of libraries rather than in any other way. Would that a word to the wealthy were as sufficient as it is reputed to be to the wise.

"Les Feux du Couchant."—In *Le Progrès Médical* for April 16, 1921, xlix, 16 is reviewed the latest physiological and medical romance of Michel Corday, with the above title. This has to do with the supposed fact that in the decline of a man's life—say from 50 to 60 years—his passion for the other sex undergoes a sort of reawakening after having first undergone a gradual and considerable subsidence. He makes his medical character, Dr. Madelin, inform the hero, who is his old friend, that at the threshold of old age there is apt to supervene a sudden and intense passion for some person of the other sex. It is the final flare-up of passion. As a rule it is not serious, but at times pursues an acute course. The hero, Faugeat, is not a seasoned hand at the game as was Baron Hulot in Balzac's *Cousine Bette*. He is a magistrate of unblemished character, father of a family. His age is fifty-eight. His senses no longer respond to the attractions of his wife which have faded. None of the other women whom he encounters has roused his passion. At last through a theatrical director friend he chances to meet an actress twenty years of age and beautiful. A miracle happens and in falling in love with her he feels that rejuvenation has occurred. She is his complement, his affinity. For producing this transformation in him nothing is too good for her. Desperately enamoured he performs one foolish act after another. He begins to dissipate his fortune and his children's fortunes, until he learns that the innamorata has played him false; this discovery with an opportune illness brings him back to reason. The book, unlike many romances, really has a moral.

Sydenham's Recognition of Epidemic Encephalitis.—Attention was called long ago to Sydenham's description of a fever which first appeared in Great Britain in 1674 and which might have been an episode of epidemic encephalitis. According to Grenier de Cardenal (*Journal de Médecine de Bordeaux*, March 25, 1921, xcii., 6) it has escaped the attention of the profession that the same author described a return of the same ailment in 1685, not long before his death. Of two French editions of Sydenham's works, only one contains the account of this recrudescence of the disease. The latter appeared in the month of February and persisted for about a year, being disseminated throughout England. The author himself recognized it as a return ten years later of the earlier disease and moreover it appeared in the midst of an influenzal epidemic.

There were two leading cerebral symptoms, coma and delirium, the latter wholly of the tranquil kind. It was dangerous to allow these subjects to sleep and the author apparently kept them up and about as far as possible. He speaks of certain motor phenomena, chorea-like and convulsive, which may have represented the myoclonic form and attributes to them a bad prognostic significance. These, however, may have been purely terminal phenomena. Most singular is a mention of convulsive hiccough. This, as well as the motor phenomena and delirium, appear to have distinguished the second from the first visitation, which was lethargic throughout. The hiccough was neither severe *per se* nor was it of bad prognostic significance.

ON THE PREVENTION OF VENEREAL INFECTION.*

BY THOMAS E. SATTERTHWAITE, M.D.,

NEW YORK.

LAST summer I called the attention of medical practitioners to the great increase of late in the ratio of infection from venereal diseases among the British, our own military forces in Europe, and also the Canadians, contemporaneously with the recent war activities. I also called attention to the fact as mentioned by Dr. Joseph E. Moore, one of our military officers stationed in Paris, that at one time 70,000 prostitutes plied their trade there unmolested by the police. I also stated, on the authority of Morel, formerly a member of the English parliament, that wholesale infection of girls and women, in the occupied enemy zone, was caused by some of the French colored troops. This matter found its way at various times into the public prints and led to public discussion which resulted, after a time, in amelioration of these conditions, if we are to accept newspaper reports. Further, in an article published last autumn I stated that the incidence of venereal disease in Paris at the time above mentioned, was, according to Moore, about 330 per thousand, among our troops there, or about one in three, while among the British troops, there at the same time, the incidence was said to be about 200 per thousand. Now assuming that the British rate among their military in time of peace was about 50 per thousand, a pretty fair estimate, I think it is quite evident that venereal disease in Paris had at that time assumed the character of an epidemic.

But more than this, we have been told by Sir Archibald Reid, in his "Prevention of Venereal Diseases," 1920, that "nearly all the troops from France and Germany which came to him in the early part of the war were infected (p. 133), while after the American troops landed in France, 104 infections out of 100 were noted in some units (p. 272). In occasional instances, of course, two or more infections at different times, in the same individual made this otherwise impossible ratio possible. Moreover, he stated that so far as Great Britain was concerned, when he was writing his book, something like every other person in the United Kingdom had suffered or was suffering from venereal disease (p. 329). This statement is, one would think, too broad for acceptance. At any rate, I believe the loss to a nation from these diseases in health, in happiness, and in efficiency far transcends the loss from any other source, even tuberculosis, which was once held to be the most fatal scourge of the world.

But when we come to think that syphilis and gonorrhea, or at least the affections to which they may give rise, are apt to be incurable, their dangers become more apparent. Indeed, we must not forget that gonococcus infection, once thought to be a comparatively mild affair, may actually effect directly or indirectly disease in any part of the body in either sex.

That these manifestations may also be incurable or lead to fatal results, will be admitted at the present day by medical practitioners generally. Gowers once said of syphilis, and his name should carry great weight with us, "it is an incurable disease. No treatment," says he, "however thorough, will bring syphilis as a disease to an end. Syphilis," he also added tersely, "is unrivaled in its total capacity for wrecking human happiness and health and life by any other disease." As to prevalence of syphilis in these latter days, Riddell, a Canadian government official, has told us that in 1920 there were more than half a million syphilitics in Canada, and 40,000 in Toronto. How large a percentage of the belligerent troops were infected is a matter as yet indeterminate. I have thus far seen no satisfactory statistics on the matter, nor have our own statistics impressed me as to their accuracy.

But Miss Ettie A. Rout (now Mrs. Hornbrook) has stated that probably no European country had less (in 1920) than three or four more times the amount of venereal disease it had in 1913 or 1914. Incidentally, I may say it is my impression that the colored races were largely responsible for its recent dissemination. In some parts of Africa, such as Egypt, or territory adjacent to it, such as Madagascar, the incidence is, I am inclined to think, greater than in any other part of the world. It is endemic in some of these places. Reid has charged his own nation with being most active in spreading it. But I think, he may not distinguish the native Anglo-Saxon from the Colonial. The degree of infection in some colored races was alluded to in a recent public discussion that took place in England, when Viscount Knutsford told of a call of two vessels at a West India island, where he said venereal disease was "frightfully prevalent." On one ship with 650 aboard, 160 cases of syphilis were found after the vessel had left the port, the inference being that the disease had been contracted in this particular island.

Since my article appeared Miss Rout has writ-

* Read at the annual meeting of the American Therapeutic Society, June 3 and 4, 1921. (See page 347.)

ten commenting on my opposition to the so-called "preventive treatment," stating that as the result of it between Nov. 8, 1917, and March 30, 1918, the ratio of infection was reduced from over 20 per cent. to less than 3 per cent. She stated also that the licensed houses in Paris, "made the least dangerous provisions for the normal sexual needs of the men," and that they were "infinitely preferable to the unlicensed house system of London." She said in fact, "This French system, supplemented by our own issue of portable disinfectants to Anzac soldiers (Australians and New Zealanders), and aided by the American Red Cross Dispensaries and the American Army Prophylactic Stations (all of which made our soldiers welcome to their medical benefits), was responsible for the fact that Paris gave us the lowest rate of infection in 1918, whereas London gave us the highest." There was evidently great danger outside of these French houses, for she says she found that in one haul by the French police, of 100 prostitutes, 91 per cent. were infected with venereal disease. In a foot-note, however, we are naively told by Miss Rout not to put too much confidence in the figures given as to the ratio of infection in Paris, for one of the officers at the Red Cross Conference in April, 1918, said he believed a number of officers were not reporting themselves, and that in other ranks the ratio of incidence should be doubled. One reason for the lack of value in these statistics was stated to be that, after the armistice at least, it was feared infected persons might be detained during demobilization. Apparently to some extent these diseases were concealed. One must note that the friendly aid of our American Red Cross Dispensaries and American Army Prophylactic Stations to their co-belligerents was duly appreciated by Miss Rout.

According to our Surgeon General's report we are told by Miss Rout also, that "During the fifty-three weeks ending September, 1918, there have been 178,204 venereal disease cases reported under treatment in the United States Army in France. But the reports indicated that approximately eighty-five per cent. of this number entered the army already infected, that approximately only fifteen per cent. of all cases reported were contracted after enlistment." From which we must draw the obvious conclusion that our examining officers admitted to active service infected men, and in very large numbers. This would naturally, if true, shift the onus of permitting infection from the officers in the field and throw it back on the enlisting officers. It is, I think, an established fact that incidental to departure, men going into active service were often examined very superficially. In fact Miss Rout maintains that of 44,167 cases of infection in France among our men, 96 per cent. were contracted prior to their entering the service. If this be true, we evidently have to accept some of our official statistics with grains of salt.

Of course, where these venereal diseases were contracted and who is to blame for the infections will probably never be determined in a satisfactory manner for obvious reasons. And yet these diseases that are being spread all over the world bringing affliction, misery, and even death into hundreds of thousands, perhaps millions, of our families, could in the great majority of instances have been prevented. For usually they were produced by immoral practices that could have been avoided. The accidental examples of infection represent only a very small percentage of the whole.

But what has been done in the way of prevention during these fateful years? The action of the British Royal Commission of 1916 is an example of what was suggested by one association in the way of prophylaxis. It passed a series of recommendations, such as that greater opportunities should be given for treatment of the infected; medical men and students should be afforded better chances to study the diseases; there should be better cooperation between associations undertaking to care for the infected; and courses of lectures should be given showing the dangers of infection. This might be called the Soci-educational Plan. The main issue was avoided. In fact it has been alleged that the incidence of infection increased under the plan. It probably was so. The disinfectant method, however, was largely recommended and to some extent put in practice by men such as Sir Archibald Reid and others. It was recommended by the British Society for the Prevention of Venereal Disease, though opposed by the British National Council for Combating Venereal Disease. Various disinfectants were used, such as calomel in ointment form, solutions of the bichloride of mercury and of protargol, and permanganate of potash, also green soap. The disinfectants were put in vials or collapsible tubes. Also there were furnished pledgets of absorbent cotton, syringes, nail brushes, and towels. These comprised the contents of the prophylactic packets made extensively for the use of the soldiers. This method might be called the Prophylactic or Direct Method. Unfortunately for its efficiency the outfits were often used after, not before exposure. After the horse had been stolen the stable door was locked. But the men were willing to take the chances. Women of the prostitute class, however, the most dangerous, seldom, it has been said, would take prophylactic treatment, and for various reasons. Sometimes they did not realize they were infected; perhaps they were unwilling to take the time for disinfection; or perhaps they knew that effectual disinfection was very difficult and not always possible even by experts. In this connection it may be said that the examination of public women as practised abroad, has sometimes been so improperly done that noninfected women have been infected, the reckless carelessness or indifference of the examiners actually carrying the disease sometimes from one to the other. Even in New York City our Venereal Disease clinics have not been what they should be as to cleanliness and other requisites. We have among us now a class of individuals, and it is not small, who look with indulgence on promiscuous intercourse, at least in so far as that they advocate chiefly methods in which disinfection before or after exposure is the cardinal point. This plan is practised in both our military and naval forces and those of Great Britain, though in the case of the latter it has met with considerable opposition, notably in clerical and legislative circles.

The other side of this question was ably seconded during his life by Sir James Paget, who said in an article on sex hypochondriasis (p. 286),

"Chastity does no harm to mind or body," and Paget's influence in his day in medical circles was second to none. Sir George M. Humphry, the famous anatomist and surgeon of Cambridge, England, has also stated that the functions of the testicle "may be suspended for a long period, possibly for life, and yet they may be sound and capable of being roused into activity," (p. 151) and Sir Thomas Bryant in quoting this clause adds (p. 754) speaking of the testicle that "unlike other glands, it does not waste or atrophy for want of use."

I had the pleasure of knowing these three gentlemen personally and they represent to me examples of the highest type of our profession.

Also the famous neurologist, W. R. Gowers, previously alluded to, has said "One method and one alone is possible in man, and that one is open to all. It is the certain prevention secured by unbroken chastity" (p. 126).

Max Huhner, one of the latest of the contributors to this subject, has confirmed this view, stating he has seen no harm in continence, but rather that it is one of the keys to a solution of the problem (p. 261). Herein is the truth. It is a key and at present the best key at hand. But there are others. One is quarantine. It was my privilege once, while in military service abroad in France, to be put in sanitary control of a small town, within the area of hostilities. The officers and men were becoming infected in increasing numbers. I was given the requisite authority and had the public prostitutes sequestrated. As a result there was a prompt abatement in venereal diseases among the military. In fact no new cases came to my notice. This incident I have alluded to already in a previous article. Such a method may be successful in military circles but cannot well be applied in civil life under our present laws in this country. But there is already a new move in the proper direction in this respect. Recently a District Court of Appeals in California upheld the right of a local health officer to detain and quarantine persons having a venereal disease.

Such legal action is not an infringement on the liberty of the individual any more than the quarantining for other infectious diseases. In the face of impending danger to society, the individual should yield his individual rights. It is done in tuberculosis and in various other diseases and the same rule should apply in venereal diseases, which, as I have said, are much more dangerous to our life and well-being.

But there is a third method. It is also a legal way. Take the Swedish venereal disease law, which went into effect Jan. 1, 1919. It provided in effect that: (1) every person with venereal disease was to be treated appropriately and so prevented from infecting others; (2) the source of the contagion was to be sought and suppressed, and (3) penalties were to be imposed for exposing others to contagion. In these matters, all were made to stand equal before the law. Individual rights must be subordinated to collective welfare. At first the returns from this Lex Veneris showed hardly any reductions from preceding figures, but against 3,355 cases at the end of 1919 there was a drop to 2,495 in 1920 in one locality. In Denmark, also, there has been a move for betterment. If, for example, a citizen should undertake now to keep a public brothel or rent rooms for immoral purposes he would be liable to a prison sentence. In our own country, too, the Supreme Court of North Carolina has approved a judgment in favor of a wife who has asked for punitive damages because her husband infected her. Since then two other State courts have held that the wife has a right to recover damages for injuries to her, as in the case just cited.

It can hardly, therefore, require much vision to see that woman, being no longer a chattel, may demand protection by the State against conjugal infection and that this needed protection will be afforded her eventually by the country at large. But it is the fashion of the day, as I have said, to advise other methods. And yet I do not believe that much has been accomplished by such efforts as have been made in the way of prevention by the United States Public Health Service, boards of health, and private or semiprivate associations to combat venereal diseases through the instrumentality of public lectures, posters, and publicity in general. These methods have some value, I admit. Some of them emphasize, however, a popular fallacy that prophylaxis can effectively *prevent*. Even the friends of disinfection do not seem to realize that it is effective so far as we can learn in only about two-thirds of the instances where it is employed. Assuming, as we may, that disinfectants kill the gonococcus and the spirochete in vacuo, this is a very different affair from destroying the germ in the living person. Miss Rout, indeed, has told us, and one may very well believe it, that "wherever prophylaxis was properly applied, at least two-thirds of the cases of venereal disease were eliminated." But what about the one-third of failures?

Now with the exception of accidental cases, chastity and the strong hand of law do offer chances that we may eventually master this worst of all international plagues now threatening the whole civilized world, just as Europe was threatened by syphilis, the "great pox" of the middle ages.

Disinfection undoubtedly has its place as a precaution against contagion, and as a curative measure, but it should always be remembered that the so-called prophylactic methods protect to a limited extent only.

Also it should be realized that limitations of the danger do not tend to discourage improper relations with their attendant dangers. In fact, they encourage it. Infection is always possible and probable so long as promiscuous intercourse is practised with women, whether prostitutes or others.

7 East Eightieth Street.

Postencephalitic Mental Disturbances.—Guinon states that these are far from rare and comprise excitation and change of personality—once indeed for the better. Comby found these disturbances especially common in children and anticipates that the ranks of the insane will be recruited from this source.—*Bulletin Médical.*

Is Sodoku Transmitted by Insects?—If, as is mentioned by Frassit, the socalled ratbite disease is also transmitted through bloodsucking insects this name will have to make way for another, based on the particular spirochetosis involved. The course of the disease and its control by salvarsan bespeak this kind of origin, even if the particular spirochete has not been isolated. There is no apparent reason why the rat might not behave as a reservoir for insect transmission.—*Revista Espanola de Medicina y Cirugia.*

SOME PRACTICAL OBSERVATIONS ON ENDOCRINE THERAPY.*

BY J. M. ANDERS, M.D., LL.D.,

PHILADELPHIA, PA.

IT may be premised that a summary of the more practical phases of endocrine therapy is much needed by the present-day clinician. That the subject occupies a commanding position at present no one will deny; but it is equally true and of signal importance to recollect, that some of the claims advanced by certain writers for hormonopoietic products are not supported by undoubted facts. Apparent advances in certain directions have too often proven to be kaleidoscopic. The chief weakness of glandular therapy has lain in our inability to discover and interpret the functional interrelations of the various endocrine organs.

With the progress, which we owe to the labors of Sajous, Ord, Kendall, Janney, Osborne, Goetch, and others, of exact knowledge of the subject, the limits of usefulness of animal extracts are gradually being settled; and the time has arrived when a broad line needs to be drawn between those endocrine remedies which are practicably worthless in certain conditions at least, for which they have been vaunted, and those that are worthy of general employment to meet certain, definite indications. This can be done only by subjecting each glandular preparation and its uses to critical analysis, interpreted in the light of experience and experimental investigation. Pure empiricism in the use of animal extracts, be it remembered, is incompatible with medical standards of progress in therapeutics. Again, individual experience is, as a rule, too small to base thereon reliable inferences as to their value.

Disregarding the centuries spent in unprofitable speculation and fruitless investigation foreign to the purpose of this presentation, attention will be directed only to the more recent acquisitions to our knowledge of opotherapy and its application to the treatment of disease. It is regrettable that firms manufacturing these products issue pamphlets which purport to give the scientific investigations on which the claims set forth with respect of the extracts are based. Whilst this historic information may be accurate, in some cases, it needs to be verified by reference to scientific literature in all, before it is accepted as authentic and complete. True it is, however, that certain firms will be found to publish reliable information in every detail.

In addition to the clear clinical indications for the use of glandular extracts we must also concern ourselves with their supplementary effects. Moreover, we must not be unmindful of minor degrees or earlier stages of dysfunction, when it is difficult in the extreme to recognize any of the features which ordinarily make up the characteristic syndromes. These, however, call for and are readily amendable to appropriate specific organotherapy. In this connection the fact that primary hyper- or hypofunction of a ductless gland will in its course alter the functional activity of others is to be stressed, so that indications may be presented at times for the use of multiple extracts. Polyglandular preparations, however, must not be resorted to until clear and convincing evidence that more than one of the several glands are deranged as to function. It is always worth while to attempt to identify the gland solely or principally at fault, and to make trial of a single extract at first, if the promotion of our knowledge of glandular syndromes and their treatment is, as it obviously should be, desired. An accurate diagnosis by exclusion of the primary involvement of a single gland, therefore, must precede successful endocrine therapy whenever practicable. Cases, however, are met with in which a diagnosis can be made only tentatively. In such, the cautious employment of corresponding glandular extracts which are to be advised may serve to confirm the diagnosis.

In no case, however, of a mild or ill defined form of glandular dysfunction should these agents be resorted to after a superficial examination, but only in those in which a close scrutiny of the history, clinical data, and laboratory aids has been made and carefully weighed. Lawrence[1] has emphasized the value of a careful history which gives more valuable evidence in the earlier stages of any disease than all other methods of examination. He well says "Physical examination will exclude organic disease, and laboratory tests are extremely useful in determining the degree of abnormal function, but the history, if the symptoms are properly elicited and valued, not only discloses the nature of the derangement present, but gives a measure of its effect upon the patient. If properly analyzed, the evidence it affords is not indefinite, but affords, especially in the case of the internal secretions, a definite basis for differential diagnosis."

It is particularly important to note the basal metabolic rate in suspected thyroid or pituitary involvement. For example, there is no better criterion of slight though positive deviations from the normal either toward hyperfunction on the one hand or hypofunction on the other of the thyroid gland than the rate of metabolism. This, then should serve as a guide to endocrine therapy, if the history and symptoms presented are confirmatory. A complete diagnosis embraces the stage of dysfunction encountered in the individual case. In treating cases of glandular derangement, the clinician must also meet the hygienic and therapeutic indications of the predisposing factors as well as any associated diseases in the given case. The writer has learned from personal experience to appreciate the fact that the beneficial effects of the class of products under discussion are more limited than certain enthusiasts would have us believe.

If the sufferer be the subject of disease of the heart or kidneys, preparations of the thyroid and pituitary glands are not without danger and may be fatal. The writer recalls a patient with advanced myxedema and associated mitral regurgation, which occurred at a time when a cautious increase of dosage was not generally observed, and a maximum of 5 grains t.i.d. suddenly proved fatal. We know too little about the subject of endocrine diseases and their etiology and associated pathological states to warrant the indiscriminate, not to speak of the reckless, use of animal extracts.

Again, the clinician has to deal with the so-called "ductless gland neuroses." Hemmeter,[2] Friedman,[3] and other writers have, with justice,

*Read at the annual meeting of the American Therapeutic Society, June 3 and 4, 1921. (See page 349.)

claimed that all ductless gland disturbances may manifest themselves clinically without macro- or microscopical alterations of these structures. W. Langdon Brown[4] discusses the relationship of the sympathetic nervous system to the endocrine glands and strongly emphasizes the interdependence of the latter and the vegetative nervous system. In this connection the following quotation from his paper is of special interest: "Designed as an intensive preparation for action or defense, the sympathetic response may be so dissociated, perverted, or prolonged as to produce through the thyroid gland Graves' disease with its danger to life, through the pituitary body, diabetes insipidus with its attendant discomforts, through the pancreas and other endocrine glands, excessive mobilization of the blood-sugar, which is the first stage of the metabolic disorder that culminates in diabetes; it may disorganize digestion by exciting spasm and atony in stomach and bowels, and inhibiting the secretion of digestive juices; it may keep blood pressure at a level which is inappropriate for the task of the heart and the arteries. These effects are not necessarily distinct—thus, intestinal stasis from sympathetic inhibition causes poisons of putrefactive origin to be absorbed, which in their turn lead to vasoconstriction, and hence an unduly raised blood-pressure." Obviously, a knowledge of visceral neurology is essential to the successful management of diseases of endocrine origin.

Langley and Elliot claim that epinephrin in all its actions on any organ behaves the same as electric stimulation of the afferent sympathetic fibres of that organ. Moreover, it is well understood that if the organ extracts contain any protein, there is an added protein therapy effect. There is much evidence available to show that both suprarenal and pituitary extracts increase the immune reactions, as shown by their effects upon the agglutinins in typhoid and other fevers. Again, in this power to promote the functional capacity we have an explanation of the hemostatic action of organic preparations and, similarly, of the benefits from transfusion of blood.

Whilst hitherto the application of these principles has been largely empiric, recent advances in our knowledge of organotherapy enable us to command "a substituting hormone therapy, as in thyroid treatment of myxedema; a symptomatic hormone therapy, as in thyroid treatment of obesity; a ferment therapy, as in supplying the finished pepsin or a hormone which stimulates some special secretion; a hormone therapy seeking to utilize the reciprocal and antagonistic action of the endocrine glands, and finally, we have the protoplasma activation therapy as in parenteral protein therapy." (Borchardt.[5])

Treatment of Individual Syndromes.

Acromegaly.—Opinions differ widely as to the effects of pituitary extracts in acromegaly, which is due to overactivity of the anterior lobe of the hypophysis. Kuh and Favorsky[6] have noted distinct improvement in the subjective and even the objective symptoms, while Landois and Cesbron[7] used various preparations and for extended periods, and were led to the conclusion that they are entirely ineffective. My own personal experience of the use of pituitary extracts in this disease has not been encouraging. Without doubt, a recognition of the early symptoms of pituitary dysfunction, including commencing skeletal overgrowth, offers opportunity for achieving the best results obtainable from the use of the desiccated gland. Among these are undue somnolence, aversion to muscular effort, and altered carbohydrate metabolism, as shown at times by anaphylaxis or slight glycosuria or both.

The synergistic functional relationship existing between the ductless glands is nowhere better shown than in acromegaly. For example, both myxedema and Basedow's disease may form part of the hypophyseal syndrome, as indicated above, the former during the more advanced stages of disease of the pars anterior, as a rule. In cases of acromegaly in which symptoms of myxedema are associated—an expression of functional insufficiency of the pars posterior—the utilization of thyroxin in the treatment in small daily doses, is attended with strikingly favorable results. In two cases of this combination occurring under personal observation, distinctly curative effects were observed from the use of this agent. Not only were the more characteristic myxedematous deposits removed, but also other distressing manifestations, were in great part relieved, such as the headache, irritability of temper, and insomnia. In the treatment of these two cases, the thyroid preparation was used alone, commencing with small doses which were slowly and gradually increased as the efficiency of the remedy became demonstrated by the results.

In this connection the fact is to be stressed that the use of ready-made combinations before two or more single products have been tried is illogical and tends to hinder rather than to promote progress in organotherapy. In diabetes insipidus, the administration of pituitrin (1 c.c. night and morning) is usually followed by a urine which is normal as to amount and concentration. Per contra, high blood pressure presents a contraindication to the use of extracts of this lobe.

Myxedema.—For cases of hypothyroidism there is, as is well known, a sovereign remedy. The necessity for employing thyroxin, in small dosage (gr. 1 80) so as to avoid toxic effects needs to be constantly impressed upon the mind of the medical profession. Suitable measures must also be directed to the relief of any complications and near and remote etiological influences in the individual case. There is a group of cases in which the symptoms entering into the syndrome are less obvious than in typical cases of myxedema. It is sometimes with difficulty that the significant features can be culled from the mass of data at hand, but so-called myxedema fruste presents several at least of the following features: "Irritability of temper, malar flush, apathy, neuralgia, headache, impairment of memory, tinnitus, especially on lying down, slight deafness, slowness of the mental processes, undue susceptibility to cold, weak digestion, constipation, swelling of nasal mucosa, yellowness and slight thickening of the skin and subcutaneous tissues, often confined to certain regions of the body (lower eyelid), early fatigue on exertion, and a moderate degree of anemia. The thyroid is usually smaller than the normal. It is to be recollected that in this variety cutaneous eruptions, such as

eczema, psoriasis, and urticaria may be present."

In these mild and earlier stages of thyroid insufficiency, it is not only possible to effect a symptomatic cure, but also to bring about, by enjoining absolute rest, a generous diet and the judicious use of thyroxin, a restoration to normal function of the endocrine gland at fault, in some cases at least. Such cases often follow infections or prolonged overstrain and the like.

Exophthalmic Goiter.—There is no glandular extract that has a well established reputation in the treatment of chronic hyperthyroidism. Hoppe,[9] however, has shown to his own satisfaction that corpus luteum is highly serviceable and that the patients can thus be kept in a comfortable condition. Careful dietetic, hygienic, and symptomatic treatment should be carried out while this agent is being exhibited. This method of treatment is based on the assumption of the interrelation between the thyroid and the ovaries in the female and the interstitial glands of the testicle in the male.

In my view a trial should be made of the posterior lobe of the pituitary in selected cases of hyperthyroidism. The thyroid may be observed to diminish in size and the symptoms of the disorder sometimes subside, wholly or in part, as the result of the administration of infundibulin. The effect on the metabolism is noteworthy, slowing the rate, thus favoring the storage of lime salts.

Here it is well to recollect that exophthalmic goiter and myxedema are not, as formerly believed, diametrically opposed to one another in their pathogenesis and symptomatology. Janney and Isaacson[10] have shown that similar metabolic disturbances may be present in both hyperthyroid and hypothyroid states and also that their blood-picture is practically identical. Clinicians should be constantly on the lookout for certain symptoms of myxedema in association with those characteristic of the hyperthyroid syndrome. For example, the presence of some of the features mentioned above may be noted and should lead to the judicious use of a thyroid gland preparation. The effects produced in carefully selected cases are truly remarkable in my experience.

Hypoadrenia.—The syndrome associated with both acute and chronic adrenal insufficiency has received much recent attention. The former manifests itself suddenly in diphtheria, typhoid fever, influenza, severe measles, malaria, scarlatina, and other acute infections in "rapid syncopes, with hypothermia and asthenia resembling shock." Maranon[11] has found small suprarenals with little adrenalin and cholesterol at autopsy. In these cases in which collapse is found adrenalin extracts of the whole gland, 3 mg. four times daily, should be administered. In severe types, adrenalin administered hypodermically (dose 0.5 mg. every 2 hrs.) is to be used. In the collapse of an etherized individual or one who has lost blood, larger doses than are usual, 5 to 6 mg. administered subcutaneously, are demanded.

In chronic types of hypoadrenia of suprarenal origin, 5 mg. of adrenin per day is indicated. The drug should always be administered in fractional doses at regular intervals throughout the twenty-four hours. "The injections should never exceed 0.5 mg. at any one point, though as much as 2 mg. can be given at one time." (Sergent). The writer has found the use of the desiccated gland administered *per os* without effect in some cases and in such advises a trial of adrenalin by the subcutaneous route.

In conclusion it is desired to state clearly that there are many uses of the glandular extracts in as many widely different conditions in regard to which our knowledge rests on sure foundations, but these do not fall within the scope of this article. I have considered in detail only certain aspects of substituting hormone therapy and the antagonistic or reciprocal therapeutic application of the glandular extracts. I have also endeavored to suggest principles, which should govern us in making use of these medicinal agents, rather than a complete discussion of all phases of the subject, which would be impossible within the time limit of this paper.

THERAPEUTIC USES OF PITUITARY GLAND SUBSTANCE.*

By BEVERLEY R. TUCKER, M.D.,

RICHMOND, VA.

PROFESSOR OF NERVOUS AND MENTAL DISEASES, MEDICAL COLLEGE OF VIRGINIA.

DURING the last few years the study of the pituitary gland has advanced with extreme rapidity, and, as is usual when this is the case, there has been a great deal of misconception, physiologically and pathologically, regarding the gland, and considerable looseness and inaccuracy in its therapeutic administration.

That the pituitary gland is probably the leadhorse of the endocrine system seems to be indicated by the fact that it is necessary to life, that it is of major importance in the regulation of stature, of adolescent change, of carbohydrate metabolism, and that it is the most protected, in situation, of all the organs in the body.

It is not the purpose of this paper to go into the anatomy and physiology of this gland except to say that when we consider pituitary therapeutics we must bear in mind that the secretion of the anterior lobe has, physiologically, to do with skeletal and genital development, and the posterior lobe,

*Read at the annual meeting of the American Therapeutic Society, June 3 and 4, 1921. (See page 349.)

including the infundibulum, with carbohydrate metabolism and unstriped muscle-fiber tonicity. The whole gland combines these functions. There are many other subsidiary functions which may be attributed to one lobe or the other.

When we consider the pituitary secretion we must ascertain whether an especial lobe, or the whole gland, is oversecreting or undersecreting. We must divide secretory changes of the anterior lobe, which has to do with osseous and genital development, and also of the whole gland, because the anterior lobe is implicated, into preadolescent and postadolescent changes. In considering changes in the posterior lobe secretion this division is not necessary because the posterior lobe, including the infundibulum, does not control the adolescent changes of skeletal and genital growth. We should also try to determine whether any change in secretion is chronic or transitional in character.

Certain tests are useful in the consideration of pituitary cases and we may be aided by a sugar tolerance test and blood sugar estimation. Another test, known as the pituitrin test, is used, but it has not been done over a sufficient period of time to draw definite conclusions.

Radiography of the sella turcica is of very definite importance. In all cases in which the pituitary is radiographed it is well to take both the flat and stereoscopic plates. The changes found vary greatly in the normal cranium but there are certain changes quite indicative. Hypopituitary changes consist of clubbing and enlargement of the posterior clinoids and, at times, they may actually bridge across the sella and meet the anterior clinoids. There may be seen in some cases roughening and filling in of the dorsum sellæ. Thus we have space-restricting encroachment of the sella, limiting, we believe, the secretion of the gland. In the *hyper* cases the sella is enlarged, the floor is smooth, the processes are often spread out, and, not infrequently, the processes are partly absorbed. The sphenoid and frontal sinuses in the hypo cases are usually small and in the hyper cases large. There are also various changes in the hand and other bones which we will not take time to consider.

In the investigation of abnormal pituitary states we should not forget that the gland must not be considered alone, and that the sugar disturbance of pituitary states is related to, and may be confused with, the carbohydrate metabolism of the pancreas. We know that the posterior lobe has to do with blood pressure, but this must also be considered with the state of the suprarenal glands, and the cardiovascular apparatus. Body hair distribution is partly a pituitary function, but the suprarenals and the gonads are also concerned with hair distribution. The pituitary helps to regulate body growth, but so does the pineal gland. We should remember that both pituitary and thyroid states have to do with moist or dry skin, oily or dry hair, loss and gain of weight, and with nervous poise. We must also realize that when the pituitary gland is affected other of the endocrine glands may be disturbed because of its affection, while, on the other hand, some other gland may be affected and alter the pituitary secretion. Hence, any endocrine gland disturbance is, through hormonic action, polyglandular. Much confusion disappears if we can satisfy ourselves by clinical and radiographic evidence that the pituitary is the gland paramountly affected.

I approach the subject of the details of pituitary therapy with a considerable degree of hesitancy because it is still in the formative stage, but, on the other hand, unless our views and experiences are disseminated they can neither be controverted nor adopted.

The physiological importance, and hence, by inference, the therapeutic potency of pituitary gland substances may be imagined when we consider that a few drops of pituitrin will precipitate the birth of a human being into the world from an inert uterus, while the internal secretion of this gland determines whether the man is to be a dwarf or a giant, changes him from a youth into an adult and may make an individual an effeminate man or a masculine woman. It may deform our features, alter our personality, upset our emotions, blight our mentality, throw us into convulsive seizures, or destine us to be a corpulent and jovial Falstaff or a hairy, aggressive Esau.

In conditions of *over*secretion our therapy is blocked, unless there proves to be some value in treatment by *x*-ray flashes which is being tried out, save by surgery or the administration of other ductless gland substance which would tend to maintain an hormonic balance. In the case of surgery sella decompression has been practised, but its indication is not definitely determined. It is true, of course, that Cushing, and others who have followed him, have made the removal of pituitary tumors a comparatively safe brain operation, but this paper is concerned only with the medical aspect of the subject. In the case of the antagonistic action of other gland substances, we have not advanced, as yet, far enough in our understanding of endocrine hormones to lay down definite rules of therapy.

It is in the study of states of *undersecretion* of the gland that we may speak with more positiveness, and, in certain instances, confidently predict our results. Among the less frank hypopituitary states may be placed acromegaly and the pituitary adolescent psychoses.

Acromegaly, as we know, is accompanied by hyperplasia of the bony parts, especially the zygoma, superciliary ridge, hands, and feet. The soft tissue, in certain places, is enlarged, the hair is coarse and dry, the complexion is sallow, the hands are spade-like in shape, and polyuria, polydipsia, glycosuria, and various subjective sensations are frequently present. Acromegaly is sometimes a symptom of pituitary tumor, at other times there is a hyperplastic condition of the gland itself. Acromegaly is usually seen in the adult, and the writer feels that there may be present an over-activity of the anterior lobe and normality or under-activity of the posterior lobe. Pituitary therapy in these cases is chiefly symptomatic and confined to the administration of the posterior lobe extract.

The psychoses of hypopituitarism usually occur during adolescence and may be preceded by a preadolescent hyper-, normal, or hypo-pituitary state. During adolescence, frequently due to illness or injury, a marked diminution of pituitary secretion takes place and the patient has so much psycho-

motor retardation that the condition resembles dementia præcox. Repetition of movement is common, as are drowsiness, slovenliness, and inability to concentrate attention. Some patients show truancy, wanderlust, bizarre behavior, and at times hallucinations.[1] Whole gland pituitary extract has cleared up some of these cases.

The frankly hypopituitary states should be divided into two classes, the chronic or static, and the transitional. In the static cases there has been evidence of undersecretion of one or the other of the lobes, or the whole gland, since early childhood, and in the transitional cases, usually following illness or injury, there is a more or less sudden let down in the pituitary secretion.

Pituitary Epileptic States.—In 1914,[2] 1916,[3] and 1919,[4] I published papers on pituitary epilepsy. In these studies it was found that convulsions, in no way distinguishable from those of so-called idiopathic epilepsy, occur from undersecretion of the pituitary gland. To make the diagnosis of pituitary epilepsy three essentials must be borne in mind: (1) The convulsions must make their appearance during the period of adolescence. (2) The case must present clinical evidence of hypopituitarism. (3) Radiographic evidence of pituitary undersecretion must be present. Of seventeen static cases of this character which have been studied over a period of years we find that in nine of them no attacks have occurred for over three years. Four cases have been taken off of all medication for several years and the attacks have not returned. Two of the remaining cases seem definitely controlled by pituitary feeding, four were improved to some extent, one was not improved but had a bad family history, and one was lost track of. Of the eleven transitional cases reported in 1919 the results were not nearly so striking and it was found that they did not take the medicine as regularly. However, definite improvement occurred in eight of the cases. As a rule the whole gland extract was given in doses of from six to twelve grains daily. In certain cases of genital and skeletal developmental delay the anterior lobe is more effective. At times oral feeding is reinforced by hypodermic administration.

Obesity.—Obesity should be treated, after a pituitary diagnosis is established, by careful pituitary feeding of the posterior lobe, or at times of whole gland in those cases which have also skeletal and genital underdevelopment. In these cases it is often necessary to combine either thyroid or ovarian extract with the pituitary. Pure pituitary obesity gives breast-girdle and flank fat and a rounded contour over the pelvic girdle, while ovarian obesity is marked by excessive trochanter fat. Under the heading of pituitary obesity may be placed the condition known as adiposis dolorosa which occurs during postadolescence and is characterized by rolls or cakes of fat that are painful upon pressure. These cases do not respond so well to endocrine therapy as those of simple obesity.

Pituitary Headaches.—These are deep seated, bitemporal headaches, the location of which is frequently described by the patient with the gesture of putting the forefingers to the temples and pointing them toward each other. These headaches may be transient or continuous. The patient may feel as if a marble or some other object is moving about at the base of his cranium. Pardee described these headaches in 1919.[5] At times the sella turcica is constricted, or the gland may swell and stretch the capsule, and pressure may even be exerted upon the cavernous sinus. An upper temporal quadrant restriction of the visual fields may be found. The headache usually ceases upon feeding whole gland pituitary extract. These headaches not infrequently follow some infectious disease and may be due to a toxic condition or inflammatory congestion of the gland.

Diabetes Insipidus.—Barker and others have called attention to the relation of the syndrome of polydipsia and polyuria to undersecretion of the pituitary gland. These symptoms are usually promptly relieved by daily hypodermics of posterior lobe liquid. Pituitary whole gland extract by mouth has been used, but is not generally considered satisfactory.

Dysmenorrhea, scanty menstruation, amenorrhea, and *menorrhagia* are frequently relieved by the administration of whole gland pituitary extract; or at times a liquid preparation of the anterior lobee is more effective, especially in early adolescent cases. This therapy is often rendered more efficacious when conjoined with the adminstration of ovarian extract.

Constipation due to loss of bowel-wall tonicity is helped by the administration of a posterior lobe preparation. The same is true of inertia of the bladder.

Enuresis, due to weak bladder walls, is often of pituitary origin and may be controlled by whole gland feeding or the administration of posterior lobe liquid.

Backward genital and skeletal development may be helped by the administration of anterior lobe extract or liquid. If the case has obesity in addition it is best to give the whole gland.

Reversion of sex characteristics is usually a combination of pituitary and gonad difficulties and has to be treated according to the physical and metabolic characteristics of the individual case.

Cases of true *dwarfism* and *gigantism* are not usually influenced by pituitary therapy.

Arterial Hypertension.—Englebach of St. Louis[6] suggests the use of posterior lobe pituitary extract, in combination with other ductless gland therapy as indicated, to reduce the blood pressure in cases of vascular hypertension not due to cardio-vascular-renal conditions, acute infections, etc.

In conclusion, we may feel that while much pituitary therapy is undetermined, there are many definite conditions known, in which, when clinical, radiographic, and laboratory evidence is present, pituitary administration accomplishes what nothing else will. On the other hand, the habit of giving pituitary and other ductless gland substances carelessly or empirically should be vehemently interdicted.

MORBIDITY AFTER OPERATIVE TREATMENT IN ABDOMINAL SURGERY.*

By W. WAYNE BABCOCK, M.D.,
PHILADELPHIA, PA.

THOSE who take the trouble to reexamine patients from time to time after abdominal operations must be impressed by the rather large percentage in which there is no relief from the symptoms. After operations upon the stomach, duodenum, and biliary system persistent symptoms are distressingly frequent. After operations for chronic appendicitis pain and tenderness in the right lower quadrant are not unusual, and operations for displacements of the kidneys and uterus not infrequently fail to relieve the backache and supposed reflex symptoms for which they were performed.

Three facts stand out as one contemplates these failures of operative treatment: (1) The cause of the original symptoms was extraabdominal and operative treatment was a therapeutic mistake. (2) An intraabdominal lesion giving symptoms was present, but was not recognized by the operator and the wrong operation was performed. (3) The operation was a technical failure, because it either failed to do what was intended, or added new pathological conditions that caused a continuation of the old or implanted new symptoms.

Especially important are the cases falling in the first group in which abdominal symptoms leading to operation originate without the peritoneal cavity. Much has been written about the acute peritoneal symptoms produced reflexly in disease of the thorax. An acute right lobar pneumonia with pleuritic extension causing a reflex spasm of the muscles of the right abdominal wall with pain referred to the abdomen is a not uncommon picture. In a central pneumonia with extension to the diaphragmatic pleura, the physical signs of the pulmonary disease may be difficult to elicit; but if we recall that appendicitis begins with diffuse abdominal colic, followed by nausea and later by localization of pain, with tenderness, and elevated temperature appearing as the last symptom, while chill, increase of temperature, and pain are initial symptoms in pneumonia, we will often avoid error; while the disproportionately rapid breathing, the expiratory grunt, and the early thoracic signs should immediately counteract the impression produced by the associated rigid abdominal walls and possible vomiting. Unfortunately, the nerve reflexes in the abdomen have been unduly emphasized. We must remember that pneumococcic or streptococcic peritonitis is a not infrequent accompaniment of pneumonia or pleurisy. The primary rigidity of the abdomal wall disappears to be soon followed by recurrent vomiting, tympany, intestinal obstruction, evidence of free fluid, perhaps without muscular spasm. Operation or autopsy shows an often unsuspected diffuse purulent peritonitis in these cases. In chronic irritation of the pleura, and in non-inflammatory transudations in the pleural cavity, the chief pain may be referred to the upper abdomen on the affected side. Without an examination of the chest the consultant may be led to consider biliary, gastric, or some other form of upper abdominal disease as the cause of the symptoms.

Of the more chronic affections, the gastric symptoms of pulmonary tuberculosis have led to many useless operations, especially for gastric ulcer. Frequently the chief complaint of the patient is gastric distress, often apparently increased by taking food and associated with vomiting. Not infrequently the patient says he has vomited quantities of blood, and the cough and other respiratory symptoms are so slight as not to attract the attention of either the patient or consultant. In young women especially and also in young men who give symptoms of a chronic or subacute gastric ulcer, the thorough study of the chest is much more important than a fractional meal, and well made radiograms of the chest are often more illuminating and less subject to error than the roentgenological study of the stomach. Someone has said that we may depend upon the *x*-ray evidence as to ulcer of the stomach in 10 per cent. of the cases. Personally, I have found that ulcers apparently shown by the *x*-ray plate or fluoroscope, but not clearly confirmed by the associated clinical symptoms, can rarely be demonstrated by operation. Unless the roentgenologist has unusual skill, is a good clinician, or is a lucky guesser, you will often find that hearing and not seeing is believing, that the history tells more than the fluoroscope. If you ignore the chest and depend on the average roentgenologist for your diagnosis, you may operate in many cases for gastric ulcer when the lesion is pulmonary tuberculosis.

Besides the evidence from the thoracic examination, the patient with pulmonary tuberculosis usually has a true anorexia, an aversion for food, while the patient with ulcer has hunger and eats to obtain relief or to satisfy his appetite, or refrains from eating because of symptoms, such as pain or vomiting that he knows will follow. Mayo Robson estimated that 20 per cent. of patients with gastric ulcer develop tuberculosis. Probably it is more correct to say that in over 20 per cent. of the cases the gastric symptoms indicate pulmonary tuberculosis.

I find I have been prone to forget that attacks of severe epigastric distress occurring often at night with nausea and at times vomiting may indicate a serious myocardial lesion, an aortitis, or disease of the coronary vessels, rather than gallstones or cholecystitis. As a rule, the patient is of middle or rather advanced age, usually obese, and on casual examination the heart sounds heard indistinctly through the thick walled chest may be considered normal or nearly normal. Often the patient is referred to the surgeon with the history of having been treated for months or years for a

*Read at the annual meeting of the American Therapeutic Society, June 3 and 4, 1921. (See page 350.)

chronic digestive disturbance, often the internist recognizes the existence of cardiovascular trouble, but insists that operative relief for the very evident and distressing gastric symptoms be given. Possibly there is history of a previous operation. And with or without operation the patient's sudden death may occur in a nocturnal attack or the patient may instantly die under sexual or other excitement. When the usual symptoms of angina are present, the diagnosis is more obvious. If an operation, such as a cholecystostomy or cholecystectomy is done, the patient may greatly improve, due to the rest in bed and perhaps also the other restrictions that follow a serious abdominal operation. Unfortunately, with the resumption of the usual mode of life, the old symptoms recur and an excuse is sought—"Adhesions, too short a period of drainage, failure to remove the gall-bladder"—for the poor surgical result. Robert H. Babcock has pointed out how the myocardium may suffer from a septic focus in the gall-bladder or appendix. The converse is perhaps more frequently true—that with a passive congestion of the liver and stomach from a failing myocardium, abdominal changes with at times associated infection involving the bile and gall-bladder are not uncommon. We believe that myocardial disease advanced enough to give marked upper abdominal symptoms will rarely be permanently relieved by operation on the gall-bladder or appendix. This is not asserting, however, that a cholecystectomy or appendectomy fifteen years before might not have eradicated a septic focus and might not then have prevented or relieved the myocardial disease.

Gastric attacks due to endocrine dyscrasia or general metabolic disturbances, such as that commonly described as "bilious sick headaches," or as acute bilious attacks, are not amenable to the usual abdominal operations. Likewise, backaches due to toxemia, faulty static conditions, spinal disease, sacroiliac relaxation, will not be relieved because a retroverted, or fibroid uterus is corrected, or because ptosed kidneys are decapsulated and sutured. Neurotic patients, many of whom have merely the toxemias of an unrecognized pulmonary tuberculous, or other infection, of course will not be benefited by an abdominal operation, when the causal element lies without the abdomen. While we are more careful to avoid operations on the stomach for symptoms produced by lead colic Pott's Disease and tabes, it is not generally known that the early root pains in encephalitis lethargica may result in the admission of patients to surgical wards for acute appendicitis or cholecystitis.

In the second class of patients, where the predominant abdominal lesion is not recognized, or treated at operation, we find a sufficient number of patients to emphasize the importance, when operating, of examining and recording the condition of each organ in the abdomen as often as the exigencies of the case will permit. Too often reoperation is rendered necessary by the carelessness or error of the first operator. Gastric symptoms, reflex from an encapsulated pelvic abscess or old ectopic pregnancy, will not be relieved by a gastroenterostomy. An appendectomy will not help ureteral colic, nor will the removal of small uterine fibroids cure an annular carcinoma of the splenic flexure. A careful intraabdominal exploration with the gloved hand may save the patient from being sutured after the removal of an innocent appendix, when gallstones or gastric ulcer are present. It is to be recalled that a slight evening elevation of temperature and progressive loss of weight and strength may be the only symptoms elicited from a hypernephroma of the kidney. A mobile cecum and ascending colon are frequently overlooked and may cause persistent distress after an appendectomy or other abdominal operation.

The ascending colon should be a fairly fixed standpipe, for here 80 per cent. of the water of the food is absorbed. If it develops a mesentery and slumps down, its capacity is reduced and its attachments are such that it tends to drag down the right kidney, the gall-bladder, and the duodenum. Thus, as has been emphasized by Waugh, appendiceal, renal, biliary, and gastric symptoms may follow. We are inclined to think that neglect of this portion of the bowel has given us a considerable postoperative morbidity. It is not difficult to restore the fixity of this portion of the colon, or by plication to shorten and decrease in size redundant portions of the bowel.

In the third class, among the operations that fail to do what was intended, we would mention the removal of epiploic appendices in mistake for the vermiform appendix; the partial removal of the appendix with retention of an infected stump or of overlooked fecal concretions that have escaped from the appendix; operations for visceroptosis that fail to hold or give symptom producing adhesions; incomplete removal of sources of infection, as a simple amputation of the Fallopian tubes when there is chronic gonococcic infection of the endometrium. The drainage of a diseased gall-bladder is often followed by symptoms, as is a cholecystectomy, with obstruction of the common bile duct, or a choledochotomy with retention of a stone in the ampulla of Vater.

Too often we fail to individualize in our operative treatment and instead of doing the logical thing for the particular case blindly follow our own method or that of some brilliant teacher. How many of us take into account when we attempt a gastroenterostomy that the operation tends to lower acidity, motility, and the emptying of the stomach, and to increase greatly the irritation of the jejunum and the likelihood of jejunal ulcer, and that with an open pylorus, it is to a very limited degree a drainage operation. It is true that there are exceptions like the "dumping stomach" from gastroenterostomy described by Andrews, but such exceptions also produce troublesome pathological changes. Surely a chronic ulcer with wasting of the peptic glands, low acidity, and low motility is not to be treated like an acute ulcer with high acid values and marked motility; yet do we discriminate as we operate?

We are now constantly trying to eliminate the pathological results of such makeshift abdominal operations as gastroenterostomy. We must turn from pathology-producing operations to a more earnest attempt to restore physiologic function in our surgical treatment.

2033 WALNUT STREET.

THE PRO-MORAL CENTER:

ITS PRACTICAL RELATIONS.

By WILLIAM BROWNING, Ph.B., M.D.,

BROOKLYN, N. Y.

PROFESSOR OF NEUROLOGY, LONG ISLAND MEDICAL COLLEGE.

IN connection with the facts and conclusions presented in a former paper (MEDICAL RECORD, June 18 and 25, 1921, it is in order to call attention to the natural corollaries and to bring them, as far as practicable, into relation, if not harmony, with current views. Desirable at least is a tentative outline of the directions in which knowledge of such a center should be of use.

The aim here is withal not simply to point out its relations, important or otherwise, but to connect up this center and give it a functional setting.

What bearing or importance have these cases beyond the casual interest of clinical observations? The few commentators have been unable to get far with an unlocated center, or have regarded such cases as mere anomalies. Yet the chemist and the physicist have long noted that it is the exceptions that carry significance, that indicate something in need of further elucidation.

The new basis offers some attractive propositions and a better interpretation of various psychic and allied matters of wide interest. It seems to fit in well, and, from citations given, even to be opportune. A technical psychologist might extend warrantable inferences much further than will here be attempted. So many queries are raised and so many new viewpoints established that their adjustment will require time and cooperation. It seems wiser to present in the simplest manner a few of the more patent applications, and thus forestall early confusion.

1. *In Cerebral Localization.*—Here the value of the sign, when it occurs, is apparent. It will become more widely available when all the relations and anatomic limits of this and subsidiary centers become more exactly defined. If injury of this center is a sufficient cause of moral defect, it is warrantable in cases of like symptomatology to conclude that there is at least a functional failure of the center to act.

The principle of a moral center can also find application at times in medicolegal work.

In addition, the knowledge of this center can be of service in the working out of other functions of the frontal lobes. Especially applicable here are the two main divisions of mental activity, to be noted under Psychology (*vide infra*), as aides in the allocation of functions. A much surer basis is also afforded for determining the selective action of drugs that affect the higher cerebral functions.

2. *In Obstetrics.*—According to obstetricians consulted, a majority of forceps injuries are of other parts of the skull. Yet there were five such in the present series. The serious results of such damage to the brain evidently may not appear until late in the child's development. The relation of these facts to methods in midwifery can of course best be estimated by the workers in that field.

3. *In Psychiatry.*—Anyone who has to deal with morbid mental conditions in much variety, and who has in mind the teaching presented, will soon realize the aid it affords in the understanding of many cases. For example, part of the old monomanias, that have been batted from post to post or disowned, can here find a last resting place. Take pyromania as an illustration. Every child, certainly every boy, dotes on bonfires. Remove restraint, and he is a potential pyro of the morament type. This represents the largest class, at least in youth. Very different from this are occasional cases. The writer well recalls the string of black chars for miles on the crest of Connecticut hills, left by the pyromaniac raid of a vengeful paranoiac.

The question is continually asked: Are these persons insane? In reality this is a matter of secondary importance. The first thing is to determine what constitutes suitable provision for them, and then to see if it can be supplied. Some of these cases are committed as insane. But State hospitals do not look with much favor on this, and seem inclined after a little to let them go. Nor is it advantageous for either the morament or the certainly insane to be associated. Some other or separate system of commitment and care is required.

The much discussed theory of schizophrenia bears a very suggestive resemblance to the cleavage of mentality, noted below.

The psychiatric relations of this center can likewise best be developed by the authorities in that field.

4. *In Genetics.*—Moral abilities are heritable in the same way as intellectual. A structure is inherited, which can be of service for certain purposes up to a certain limit.

The prevention of morament troubles presents two separate problems. As the acquired condition, including the obstetric form, is due to injury, it is a question of avoiding accident, or of proper surgical care after that has occurred. The hereditary and more frequent form presents the same problem as hereditary mental defects of all kinds, with a possibility of special endocrine or other factors of its own. "I am inclined to think that this moral perversion is often hereditary" (Tredgold, "Mental Deficiency," 1920, p. 340).

Where the condition is of hereditary origin the individual should not be permitted to procreate. But in acquired moramentia the risk can be discounted.

5. *In Criminology.*—Naturally many of the severer cases of this kind land in the courts, and most of these are at some time sent to institutions. If young moraments are not favorably situated and subject to wise guidance, they take the nearest and easiest path and gravitate into some form of criminal or wild life. They constitute a favorable recruiting ground for criminals.

A better understanding of the psychology of crime is desirable. With the recognition of a separate center for control of morals it becomes possible to construct a tangible theory of criminality. A general glance at the subject must suffice.

For the present it is well to recognize that in principle there are two sources of crime, or in a general sense two kinds of criminality.* One is irresponsible and a sequence of organic imperfection in the brain; the other an outcome of bad environment. Though the latter form seems much the more

*Tredgold (*Practitioner*, 1917, 99, p. 45) evidently has this in mind when he distinguishes "defect of the moral sense" and "defect of the will."

frequent, we can but suspect that it rarely occurs without some organic basis on which it can thrive. At least we can be sure that in a large number of criminal cases in actual life there is a combination of these two elements. Many chronic criminals show in their histories a close relationship to the morament class. "Very many professional criminals present the symptoms of moral imbecility to a marked degree" (Defendorf's Kraeplin).

Are these two forms of criminality so absolutely distinct, and is it practicable for the courts to distinguish them? While this may not be entirely possible as yet, some attempts to do so have been made, in England at least, and doubtless the problem can be worked out when the necessity is felt.

If there are these two classes of criminality, they call for variant lines of treatment. If there is but one class, then that can be only the organic form given in this paper; and that form in any event is not amenable to our present punitive system. There is a general agreement of those most familiar with this type that if it is to be reached it must be in some other way than by ordinary punishment. Sense rather than sentiment is a sufficient guide here.

For the congenitals of this unmoral group, can we adapt the old jibe and say a thief is born and not made? Not wholly, as will appear from the context. But we can say that they are born with an abnormal weakness, or in medical phrase a lack of normal immunity.

For whatever reason the theory of such a center has failed to secure steady recognition. This may have been largely due to a failure to locate it. But some may have been deterred from accepting the principle of a moral center by an idea that it entails fatalism or abrogation of responsibility. Such objectors, however, accept insanity as a defense for wrong acts, and consequently need not feel their scruples taxed by this parallel instance.

If good results are possible in mild cases of this organic predilection to error, at least in the young, then there is hope for the many with less definable anatomic impediment. The establishment of the organic form is an initial step toward a scientific handling of criminality. It gives precision and definiteness, for this one type, to the continual agitation for better methods and results in combating criminality.

Here it is certain that all sentences and commitments should be indeterminate as to time. Such individuals should be restrained and treated as a special class of invalids until they can be freed as cured, or put under permanent control. It is an opportunity to try out that plan on a scale not apparently so far attained.

Certain conditions are a preliminary to success in any legal attack on this problem. No change should be made even in bad laws without at the same time putting other and supposedly better in their place.

No one should have uncontrolled authority to pardon such refractories. If the wrongdoer escapes prison on the score of insanity, that fact should automatically consign the individual to the permanent care of authorities for the insane. Or, if new evidence tends to relieve the accused of responsibility for supposed acts, this should not be put up to the Governor, President, or Pardoning Board, but to the courts that convicted, for their action. Otherwise final discharge from care should be left to the decision of their institutional guardians or equivalents.

One of the first principles, of course, in the wise management of crime is to prevent it, and an initial principle here is the exclusion of all laws that put a special prize on the commitment of forbidden acts.

An inconsistency appears in the customary dispensation of justice. Political or other crimes of intellectual origin, and hence responsive, if any are, to punitive treatment, are the forms most commonly condoned; while those more distinctly due to organic defect, and hence unamenable to retributive justice, are the ones subjected to punitive treatment. The reason for this is doubtless the uniformity of primary moral standards in contrast to the conventional which vary with race and place. The Elmira institution has, of course, long been known as the leader of efforts to correct this anomaly, with regard to one class.

6. *In Sociology.*—It is evident that a normal, *i.e.* a perfect-brained person, has a great advantage in realizing when he errs at least against fundamental morals. He is conscientious, thanks to the possession of a guiding center. Of the imperfect-brained there must be all degrees.

There are apparently amenities not included in the repertoire of these defectives, as listed above. These can be conveniently termed conventionalisms. We can thus see that there is an organic distinction between fundamental and conventional morals. The collective errors of the unmoral group, so far as due to imperfect action of the right frontal lobe, belong to the former, while those arising otherwise belong to the conventional. In fact, conventional moralities should be separated under some other head, as ethics or the "higher morality" of our courts and press. That the philosophers have felt the necessity for such a distinction is indicated by Bain's statement that "The moral at one time coincides with the ethical, at other times is coextensive with the voluntary." We can foresee a time when proposed changes in laws, ethics or customs will be identifiable as based on solid ground or on fallible human fancy.

As many moraments promptly heed a patriotic call, it can be concluded that patriotism is an intellectual and not a moral attribute.* The most advanced modern countries recognize "the right of asylum" in the case of political refugees. And similarly Lombroso recognized that political differed in character from other transgressions. It is now clear what these ideas are based on. Political strivers are intellectuals in contradistinction to the ordinary or moral transgressor whose conduct is dictated or not controlled by his moral center.

Disturbance of this center gives an intelligible explanation of certain cases (not all) of gross moral misconduct, where the individuals, lay and clerical, are nevertheless specially prominent and active in religious affairs. This crass inconsistency is a matter of such common observation as to be a subject of jest by the public, or of deep distress to the

*Cf. here, "War Patriotism in a Michigan Prison," by Hon. James Russell, in *Mich. History Magazine*, 1920, October, p. 776 *et seq.*

devout. It is easy to see that these leaders take their course without the aid of a moral center, and hence are in a sense unwitting hypocrites.

7. *In Religion.*—While the relation of this center to religious feeling, thought, and activity is of great interest, a word on its general relation thereto must suffice. All religions may have a common object. But some apparently seek to utilize the intellectual in advancing their cause, while others make chief avail of the fundamental morals.* This would give it a bipartite character, in consonance with the idea that there are two forms of the religious sense.

8. *In the Military.*—Whether or not the army attracts this contingent in peace times, entrance regulations are now calculated to exclude them. But the war call is their chance, and most of them promptly slip in—to the notable relief of the community at home! It is quite in keeping that many of them make a very favorable record at the front; especially in acts of marvelous daring and reckless bravery do they show themselves so superior as to gain merited recognition. Their success here is not due to physical bravery, as most of us understand it, but to their incapacity for fear. The late "Monk Eastman," long and but too well known about New York, as the ablest leader of the underworld, was evidently of this caste, and correspondingly misunderstood. He promptly enlisted for the late war, made an exceptional record for fearlessness, was of course, in consequence, thought to have "reformed," just naturally was fascinated by the new game of whiskey-running, resumed the only life open to his qualifications, and in December, 1920, was finally shot up by one of his associates.

Selected individuals of this class, under suitable management, can fill an exceedingly useful role in the world, aside from war. Unfortunately they are never recognized for their true worth, too often fall into the class of hunted criminals, and come to a tragic end.

In organizing bandit chasers everywhere it is an old rule to make use of all the ex-outlaws available. This plan is often best because these rovers were in the first place recruited largely from the class that is relatively or absolutely unable to fear.

9. *In Psychology.*—Here the bearings are quite as radical and perhaps more far-reaching, at least as regards the organic basis of psychology. As elimination of the moral center does not necessarily cause loss of the intellectual faculties, it follows that they are centered elsewhere than in the right frontal region. Nor is there any evidence or claim that the remainder of that hemisphere plays any larger role in that respect. It can hence be inferred that the asignment of intellectual leadership to the left or active hemisphere is correct.

From this it is apparent that the higher or emissive phases of mentality fall into two distinct groups separated anatomically by a deep vale, the longitudinal fissure, but with commissural connections. One group centers in the right and the other in the left hemisphere, with accessory qualities in affiliation with each. To the right belongs the control of morals, including criminality and sexualism,* while to the left hemisphere inferentially belong the intellectual reasoning and creative faculties with their subdivisions.

As the mental qualities on the right center definitely in that frontal lobe, it is a reasonable inference that those on the left have a somewhat analogous adjustment. Or, to put the matter physiologically, it might be said that in a very general sense, the left frontal is an activating and the right frontal is an inhibiting lobe.

This cleavage of mentality into two grand divisions has long been recognized in practical affairs. Anyone can recall illustrations. One has been mentioned under Sociology. Morris notes (*cf. first article*) that conduct is a balance between impulses and inhibitions. And in so recondite a field as psychiatry the general consensus can be summarized by Wholey's statement that, "We differentiate here the moral and the intellectual fields in mental life" —thus recognizing these as the main divisions of mental activity.

Exactness in the use of language and of many technical terms can be greatly aided. For instance, fear and timidity, tending to abate with years, belong to the organic or inhibitive, while caution and circumspection increase with the years and are evidently intellectual.

Some light is thrown on such matters as duality of mind, double personality, tales of the Dr. Jekyl and Mr. Hyde kind, etc. And the long discussion over instinct versus reason may also find some elucidation on this basis. The so-called humane instincts were referred to above. The maternal instinct certainly belongs here also, though no mention of it in this connection has so far been found.

Some things suggest a special relationship of this lobe to bodily functions and personal welfare—in which case our athletic devotees can come in for a share of recognition.

The everyday question of right and left handedness, so long a puzzle, thus proves to be a simple result of cerebral function, the intellectual and activating side very naturally taking the lead.

Cases that have improved so far as to recognize the bad character of their acts after they are done, remind one of the old quip about hindsight being better than foresight. This is like the spendthrift who sees the folly of his past expenditures, and yet if he gets more he proceeds to squander it as promptly as before.

10. *In Education.*—If the central control of morals is anatomically separated from the intellectual functions, this fact immediately assumes an important relation to education in general, quite aside from the special class of cases considered. Though this may seem an uncalled-for expansion of the subject, it serves to make the relations of the pro-moral center more real and intelligible.

The new knowledge should tend to an improved understanding of educational needs and to greater

*Fear, the psychic quality of feeling, and the control of impulse, emotion, and passion appear, from various items in the histories, to be centered here also. While some of these individuals are very irritable, in manner they are unemotional. As C. B. Burr says, "The emotions lie close to the organic (bodily) functions." "*Moral imbecility* . . . is characterized by the absence or weakness of those feelings which inhibit the development of marked selfishness." (Defendorf.)

Moraments may be suicidal, not because of regret at their misdeeds but from their lack of resistance to impulse on coming to a realization that they are badly handicapped.

scientific accuracy in methods. Different and complementary programs must prevail if the two sides of mentality are to be evenly trained.

To be versed in the subject of morals is an intellectual accomplishment. But such knowledge requires the cooperation of an efficient pro-moral center if it is to exert its proper influence on the possessor's conduct.

The necessity of developing both the moral and the intellectual is demonstrated many times in the course of history. While it is impossible here to fully dissociate conventional from fundamental morals, the facts are worth summarizing.

Viewing nations at large, it is generally recognized that those with the higher morality take the lead in the long run. It is therefore evident that morality is an indispensable part in any program of vitality and progress. But when we examine further it appears that this of itself is not all-sufficient.

For, so many times it is related that a noble, honest, humane people—a people who in moral things had advanced infinitely beyond the primitive savage and animal—had been unable to cope with all conditions. Many of these had moral standards far above those we follow to-day; they did not even dream of guile. But they succumbed. If the moral progresses chiefly the nation or people become the prey of others. This may not be creditable or ideal, but it is a recognizable fact.

And it is a matter of old observation that a community or person exclusively devoted to goodness becomes a pillar of salt—devoid of vitality. From all this it is evident enough that the moral alone, however essential, cannot suffice.

Hence if we view the world simply as to the effect of morals we come to an impasse. It is evident there must be some other and equal factor that plays a complementary role in general advance.

The other side of mental activities, as has been pointed out, is the intellectual. We therefore turn to see what that has accomplished. It is clearly a necessity for self-preservation and progress. Yet when the intellectual is predominant we see whole nations misled by over-weening and intolerable arrogance, or by a babel of unbalanced thought. Both from the present division of mentality and from the fact noted under Sociology regarding patriotic and political striving, the blame for war as an aggressive act can always be debited to the intellectual side. (To avoid misunderstanding, it may be stated that the writer has no relation to so-called peace propaganda, nor can he claim any to religious thought). Actual intellectual superiority proves to be a one-wing power and leads to their undoing. It is a matter of common homily that peoples reach an intellectual zenith, and then disintegrate through moral deficiency or decay. So here again we come to an impasse.

Whether the facts referred to are a sufficient illustration, they at least call attention to the significance of the center in this relation. We can therefore but come back to the original proposition (Rooseveltian in tone) that both phases must be cultivated if steadfastness and certainty of progress are to be accomplished. Other claimants (as hygiene, eugenics, law, etc.) may represent essentials, but all these fall under the main heads. To gain and preserve this balanced mentality must be a supreme object of civilization. And it must apply not to the few but to the many.

The object is clear; but the methods of accomplishing it are beyond the scope of this paper. It may be pointed out, however, that ordinary educational systems apply only to the intellectual side of the brain, and cannot be expected to have any direct influence on the moral. The personal control of morals cannot be integrated by any system of mere scholarly discipline. A vast amount of energy is steadily expended in moral "drive," but as improvement is sought almost exclusively through intellectual agencies, the results are not up to expectations or may even prove, on the contrary, to increase "the powers of evil."

To accomplish anything direct new ways must be devised or old ones adjusted. A couple of possibilities are noted above (*sub* Treatment). And even Rush offers ideas that may prove suggestive. This field, as a structurally independent psycho-gene, has necessarily so far been unrecognized. Tests of the moral stamina, especially in children, can doubtless be devised.

From this too brief outline it is clear that the question of moral training or education (if it be compassible) is of prime importance at this juncture. In some cases little or nothing new may be called for.* Again and more often it it as essential as intellectual development; and because of its neglect it is in greater need of consideration.

Our mentality has two wings. We cannot maintain progress when either too far overbalances the other.

54 Lefferts Place.

THE TREATMENT OF FUNCTIONAL DISORDERS OF THE COLON BY MASSAGE.

By ROLFE FLOYD, M.D.,

NEW YORK.

During the latter years of my association with Dr. Francis Delafield, 1910-1912, we became much interested in the treatment of constipation and other colon disturbances by massage, and since that time my interest in the subject has continued. While there is nothing new about the method it has yielded such satisfactory results that it is perhaps permissible to direct the attention of the profession again to it.

It is the business of the large gut to receive the fluid contents of the small intestine, to increase their consistency by the abstraction of water, to transmit them through its length, and extrude a part of them from the anus once a day as a formed stool. These results it accomplishes chiefly by mus-

*The Quaker is a concrete example of basic morals. And true to this he is non-resisting and anti-military. He is saved because he is at pains to develop the intellectual (cr. as some say, is saved by associates).

And, if popular repute has any warrant, the true New Englander has less need of intensive moral training than have some other descendants of Adam. Some think the Yankee stock decadent, or riddled with exceptions, or too much scattered to be a distinct element. But, granting them a large claim to basic morality, it may account for their ability to stand intellectual training (on the line of balanced mentality), and as a net result their concededly large influence on the life of the land.

cular activity and the absorption of fluid. Secretion of mucus from its wall probably also helps to control the consistency of the contents and facilitates their passage along the gut.

A normal large gut, moreover, contains gas, whose amount varies within wide limits. There is usually more of it after 40 years of age, and it is especially apt to collect in the caput coli. It may be derived from three sources: (1) It may be received from the small intestine; (2) it may be produced by fermentation of the contents of the large gut, or (3) it may come from the colon wall. I am inclined to believe that the latter method is more important and fermentation less a factor in its production than is usually supposed.

Functional derangements of the activities of the large bowel are matters of every day occurrence. When a person fails to have a formed stool once a day or if the daily stool is too hard or if it is too small he is said to be constipated. Such conditions are due to inefficient motor activity, or to the absorption of too much fluid by the colon wall, or to a deficiency of fecal matter, and perhaps also to an insufficient secretion of mucus.

Analysis of the feces shows that they are composed chiefly of non-digestible matter taken in with the food, of undigested food, of chemical by-products of digestion, of products of the alimentary canal and its glands, such as mucus, bile, digestive juices, exfoliated epithelium, etc., and of enormous numbers of bacteria which have been estimated by Strasburger to compose one-third of the total weight of the feces.

With this complex composition it is not surprising to find other factors than diet operative in determining the amount of fecal matter passed, and it is a fact that individuals in health produce different amounts of feces on diets very similar in quantity and quality. Under abnormal conditions wide variations in the amount of fecal matter are frequent. Thus in colitis the rule is that very little or no fecal matter is seen in the stools in the acute stage, and its reappearance in normal amount and consistency is one of the important indications of recovery. On the other hand, in some forms of colitis huge amounts of pasty feces (exclusive of grossly evident serum, mucus, or blood) are passed, so that a patient may fill a bed pan at one time.

A deficient amount of feces also occurs as a purely functional condition. I have frequently seen patients who passed only minute quantities of feces for one or two weeks and yet the whole colon and rectum remained nearly empty. A much more prolonged and extreme example of the same condition in a private case of Dr. Delafield's follows:

CASE I.—Boy, seventeen years old, of wealthy parents, living under the best conditions. In January, 1890, he had influenza and a second attack in February associated with nausea and anorexia. He began to improve in March and was taken to the country in April. His convalescence was slow and his bowels moved only once in four to six days, though he took many cathartics. In June he went to the seashore. He was gaining a little all the time. In July he could get about and play tennis. On July 28 he was caught in a squall out sailing and had to work hard. He had headache, nausea, and vomiting when he got home.

From August 4 till September 27 (fifty-four days) his bowels did not move in spite of many cathartics. On September 27 he passed a little hard feces. He next passed some hard feces on October 10 (thirteen days), and next on November 5 (twenty-six days). During this period of ninety-three days with three small hard stools he was taking constant cathartics. He was eating small quantities of bread, butter, milk, eggs, meat, and vegetables. He could go about but had headaches, sleeplessness, nausea, and occasional vomiting.

November 6 he came to Dr. Delafield for advice. He was thin and pale. The intestines were empty and it was evident that the bowels had not been moving because there was so little fecal matter to come away. He was put on a combination of mild cathartics and oil enemata. His diet and mode of life were carefully regulated. By the end of December he was passing feces nearly every day and had gained four pounds. He made a complete recovery.

This case has previously been reported by Delafield in his "Notes on the Practice of Medicine with Cases and Charts."

The ordinary method of treating constipation which cannot be corrected by exercise or diet has been to give cathartics, enemata, suppositories, or rectal irrigations, or to mix agar-agar with the food, with the purpose of increasing the motor activity of the colon or of making the feces softer.

There are many patients in whom such measures work perfectly. There are, for example, old ladies who take a pill every night and have a normal formed stool without discomfort every morning; if they omit the pill they don't have the movement. In other patients the bowels move normally most of the time but occasionally some slight change in the routine of life induces constipation which can be entirely relieved by a proper laxative dose. To such people massage has no benefits to offer.

The disadvantages of the plans of treatment outlined above are that it is a not infrequent experience that the bowels become more and more dependent on these artificial measures and will not move properly without greater and greater stimulation; that the increasing doses of cathartics and larger enemata cause explosive movements, abdominal discomfort, pain, and other unpleasant symptoms; and that they do little to remove the feeling of ill health which these patients so regularly experience.

During the last two decades great emphasis has been laid on the absorption of poisonous products by the large intestine and this organ has come to be regarded and spoken of as a sewer; the repository for "the lees of the wine of life." Many people, both doctors and others, believe that it is seriously deleterious not to have a copious movement of the bowels every day and that the emptier a large gut is kept the better for its owner. On this theory it would be an advantage for a person to have a continuous stream of feces running from the anus were it not for the inconvenience and difficulty of disposing of them.

Those who hold this faith ascribe a great number of the ills of existence to autointoxication, resort frequently to active catharsis, and irrigate the rectum daily for long periods of time; measures which often produce a good deal of discomfort and ill health in addition to the original difficulty.

In order to inform myself on the amount and condition of the feces in the colon I examined a number of colons at autopsy and kept careful notes of 35 of them. They all contained fecal matter, 5 were loaded with it, 19 contained a moderate amount, and 11 comparatively little. The cecum and ascending colon were never totally empty and

regularly contained as much or more than any other region of equal length, a finding corresponding to Cannon's[1] demonstration of antiperistalsis in this region. The transverse colon, descending colon, sigmoid, and rectum, on the contrary, were each found empty from 6 to 10 times. Most of these autopsies were on hospital patients who, presumably, had been more or less thoroughly purged and yet their large guts all contained feces. Six of the cases, however, were in persons who died suddenly by violence in apparent health; in three of these the entire length of the colon contained a large quantity of pasty fecal matter, in all of them there was a liberal amount present, and in none of them was the fecal matter fluid anywhere in the large gut.

These observations are neither extended, scientific, nor new, but they served to convince me of three things: (1) The colon almost always contains feces whether active catharsis has been employed or not; (2) autointoxication does not depend on the presence of feces in the colon, for then it would be a universal disease; (3) in health the quantity of feces in the colon is large and of a consistence greater than fluid.

It seems to me therefore, that the proper object of the treatment of constipation is to restore the normal activities of the gut; that a large intestine which is moderately full of feces and which discharges a formed stool once a day is less likely to cause symptoms and less likely even to absorb poisonous matter than one which is being kept in an unnatural condition by repeated cathartics, enemata, or irrigations; and that a great many symptoms have been incorrectly ascribed to autointoxication which are due to disturbed motor and glandular action and to variations in the contained amount of gas and feces, quite independent of the absorption of poisons.

Case II.—Mucus due to irrigations. A physician, thirty-three years old. In October, 1908, he complained of a bad taste in his mouth. Though his bowels were regular, he suspected mischief in the colon, so he took daily saline enemata for six months. Strings and masses of mucus, sometimes more than a cupful at once, came away with the enemata confirming his suspicions. As soon as he stopped the enemata he also stopped passing mucus. In November, 1910, he felt definitely sick, so he had his feces examined, but they were reported normal. Then he had his rectum looked into, but there was nothing wrong with that either.

In December, 1910, he again took a chance on the saline enemata and again discovered mucus in his rectum. He went on a milk diet and lost eighteen pounds. In February, 1911, he once more felt poorly, resumed his enemata and rediscovered the mucus. He kept on with the enemata for five months and took phenolphthalein also, though his bowels had never been costive. He was then told to stop washing out his rectum and again the mucus vanished.

When any important organ, such as the heart or brain or bladder, fails to act as it should the person does not feel well, and the same rule will apply to the large intestine without inevitably introducing absorption as the only cause of the resulting symptoms. I do not mean to say that absorption of poisons by the colon never occurs or that it is of no importance, but I do believe that undue emphasis has been laid on it and that this explanation of symptoms has often been erroneous and has led to much futile and even harmful treatment.

Massage of the abdomen has been used for many years to relieve constipation but only lately has it been done to any extent by physicians who alone are likely to have the knowledge of structure and function requisite for obtaining the best results. In the last ten years I have given over one thousand rubbings for various disorders of the colon in some 100 patients and have records of over 40 cases of constipation so treated. In three of these only was I unable to make the bowels move by this procedure alone. Some cases were lost sight of as soon as the treatment was over, but in 20 I have later reports; in 4 the constipation returned after an interval ranging from one week to four months; 14 reported their bowels moving regularly without medicine at the end of one month to two and a half years, the average date of such reports being one year after the cessation of treatment; two patients suffered a return of their constipation but reported themselves cured after a second course of rubbings.

The plan I have employed is to rub the abdomen over the line of the colon and in the anal direction for ten minutes every day for three weeks. In easy cases two weeks is sometimes enough. One difficult case was rubbed for eight weeks. Skipping a day now and then makes no difference but repeated interruptions interfere seriously with success. The first stool was usually passed the day after the first rubbing; sometimes on the second day; in one case not till the fifth day. When the bowels began they usually went on passing one normal stool a day. In some cases they would skip a day now and then, and one patient had one formed stool every other day, which was apparently her normal state.

The effect of this treatment on the general health was most satisfactory. Almost everyone who is constipated suffers some abdominal discomfort and does not feel as well as he should. On this plan, however, such symptoms disappear promptly and do not recur so long as the bowels move.

It is essential to success to stop cathartics at the first rubbing. When a cathartic or large enema was taken by mistake during a course of rubbing the bowels missed moving from one to three days after it. One of the most successful cases, Case V, illustrates the importance of this matter.

If the stools are hard or the patient's anxiety at going 24 hours without a movement is uncontrollable, an ounce of warm olive oil may be put into the rectum at night.

Case III.—Constipation after the first pregnancy, five weeks' duration; easily cured. Woman, twenty-four years old, never costive before; since her first child was born five weeks ago her bowels will not move without cathartics. The abdomen is soft and natural; nothing abnormal can be made out about the colon. She was rubbed thirteen times. The bowels began to move regularly and normally at once and have continued to do so ever since, which is now nearly two years.

Case IV.—Constipation, seven years' duration, following pregnancy; cured. Woman, thirty years old, habitually constipated since a pregnancy seven years ago, she suffers from a heavy feeling in the head almost all the time. Her abdomen is firm but not rigid. The colon contains more gas than normal. She was rubbed twenty-two times. The first stool came on the third day. After this the bowels moved regularly and well. She experienced a prompt, complete, and permanent relief from her feelings of heaviness. One year later she reported herself "very well ever since."

Case V.—Severe chronic constipation for twenty-two years; cured. Woman, fifty-two years old; for twenty-two years she has not had one movement of the

bowels without a cathartic or enema. These means often fail and on some occasions she has gone a week without a stool in spite of vigorous measures. She habitually passes one or two drams of mucus after the stool and now and then a little blood in it. She does not have pain, but is flatulent unless the bowels move well. Her appetite is good and she has nausea only in the periods of obstinate constipation. Her general health is not good and she is tired most of the time. She has had nervous prostration, and took a rest cure once. She does not have headaches and has not lost flesh. She has known for some years that she has a dilated stomach, which was not relieved by a course of lavage.

She has tried everything for her constipation, including massage three times: (1) Five years ago by a successful Swedish masseuse for about five weeks, with no benefit. (2) Two and a half years ago by a physician at Carlsbad for three weeks, who rubbed her very hard, continued her cathartics, and accomplished nothing. (3) One year ago by a physician in Paris for two months, who rubbed her gently and reduced but did not stop her cathartic. She was able to get along on the reduced cathartic dose for three months after the treatment ended and then had to resume her previous dosage.

She is a small, fairly nourished woman. The abdominal wall is firm but not at all rigid. There is a distinct thickening of the caput three inches long and one inch wide, which is tender. There are no masses in the transverse or descending colon, nor are these portions of the bowel distended or dilated. The right kidney is moderately movable.

Cathartics and enemata were stopped at once and daily rubbing begun. On the second day after, she had the first stool without medicine in twenty-two years. After this the bowels moved naturally and regularly, only missing twice. Sometimes the stools were small for two or three days, then she would pass a large one. She was rubbed thirty-two times, and taught to rub herself pretty effectively. Seven months later I saw her again; her bowels had not missed a day. She had taken no cathartic or enema, and she said her general health was better than it had been in years.

In most people the caput coli and the ascending colon contain gas enough to allow of their being mapped out by percussion.

This is the place to introduce some peculiar ideas about gas in the colon. It does not need an autopsy experience to learn that nearly every adult has gas in the caput coli and often in other segments of the large gut. It seems, however, to be the almost universal belief of practitioners and physiologists that this gas results solely from fermentation of the gut contents or from swallowed air, that fermentation is at least an unfortunate if not an actually harmful and abnormal incident in colonic digestion, and that a person would be better off if he had no fermentation and no gas. Now Cannon[2] has shown that the gut wall has to be stretched in order to contract rhythmically, and elastic gas is an ideal substance to stretch it for this purpose, especially if the solid contents are a little deficient in amount. The fact that gas increases after middle life might be due to the fact that the gut muscles then need a little more stimulation than in early adult life. The large collections of gas above an obstruction might be an attempt on the part of the body to stimulate the gut wall to greater efforts. If there were any truth in these ideas, the secretion and absorption of gas by the gut wall would produce a far more effective physiological control of the gas content than if it depended solely on increase through fermentation and diminution through passage of flatus.

Woodyatt and Graham[3] wrote a paper on "Alimentary Respiration" in 1912 which deals with this question and brings out the following facts. After analysis, early in the last century, had shown the gases in the alimentary canal to be Co_2, N,O,H, CH_4, H_2S, etc., the idea was that gases were diffused or actually secreted by the alimentary mucosa. Gerardin and Magendie tied off emptied loops of gut in dogs and observed them to distend with gas, but failed to analyze it. Planer in 1864 repeated their experiment but found no gas produced. The fact that nitrogen and oxygen were prominent components in the upper tract and CO_2, and the inflammable gases were proportionately increased below gave rise to the idea that the former were swallowed while the latter group resulted from fermentation. In any case Planer's work resulted in a general renunciation of the secretion and diffusion idea.

Certain fishes can be kept alive for many hours out of water by passage of oxygenated water through the alimentary tract. Bert kept kittens alive for 20 minutes after ligation of the trachea by inflating the gut with oxygen. After diagnostic inflation of the stomach and bowels, whether with air or CO_2, certainly most of the gas may disappear without being evacuated or expelled from the rectum. Shierbeck in 1894 proved by experiment that the stomach can secrete CO_2 and Woodyatt and Graham repeated his experiments and confirmed his results.

They then discuss the question of gastric flatulence, and acute dilatation of the stomach. Here the rapid production of gas and the results of analysis (CO_2, 24 per cent.; O, 4 per cent., and N, 72 per cent.) show that the gas cannot all come from swallowed air, and fermentation does not occur in the removed and incubated contents. They reproduced this condition in animal experiments.

I have quoted the paper rather at length to show that there is a real basis for the belief that the colon wall may give out and absorb gas. Certainly the lung does so, and so do the gills and the respiratory swim bladders of fishes. In fact, all the respiratory organs in vertebrates arise as pouches of the front end of the alimentary tract. So there is nothing inherently impossible in the idea that other parts of the canal may, to some extent, give out and take in gases.

One thing is certain, the production and absorption of gas by the gut wall furnishes a far more intelligible explanation of the colon conditions which the clinician encounters daily than can be afforded by fermentation and swallowed air alone. In my ignorance, I strongly incline to the belief that these processes of gas secretion and absorption are constantly in operation.

It not infrequently happens that there is a great deal more gas than usual. If the colon wall gets into a state of tonic contraction around it, not only is the tympanitic note characteristically resonant and drum-like over it, but the gut can be felt more or less distinctly, sometimes so plainly as to make one suspect a tumor or extensive inflammatory thickening. Such a condition usually causes constant or paroxysmal pain but not inevitably. Swellings of this nature and the attendant pain can completely disappear with a few rubbings.

CASE VI.—Evanescent tumor of caput coli with pain and constipation; cured. Woman, thirty-five years old.

Six years ago had a miscarriage, pelvic peritonitis, curettage. Three years ago she suffered from inflamed right ovary, and since then has had pain in the right lower quadrant and intermittent constipation. There is a hard mass in the right iliac fossa, 2½ inches in diameter, apparently adherent to the posterior abdominal wall, which we both took to be a thickened caput surrounded by adhesions. After one rubbing the mass was noticeably smaller and less firm; after two rubbings it completely vanished and did not recur and nothing could be felt in the iliac fossa. This woman came with a diagnosis of appendicitis, for which she expected to be operated on at once. Her constipation and pain disappeared after nine rubbings.

Tonic contraction over contained gas may also occur in other parts of the colon, but not so as to produce palpable tumors in my experience. It is a peculiar fact that a colon in this state frequently causes a secondary rigidity of the overlying abdominal wall. It is also very likely to cause reflex head symptoms such as headache and vertigo.

Case VII.—Nervous and general symptoms from a distended colon; cured. Male, twenty-eight years. In the spring of 1910 he began to have some headache and vertigo on and off. At first these symptoms were temporarily relieved by purgation, but they grew worse and more persistent. After three months he went to a stomach specialist, who put numerous restrictions on his diet and gave him laxative medicines. He got steadily worse with persistent headache, vertigo, and prostration. His abdomen felt full, though he never had any abdominal pain. He kept at work, but spent his evenings and Sundays in bed.

After nine months he came under my care. He was a powerfully built and vigorous young man, very anxious about his health. The percussion note indicated that a large part of the colon contained too much gas under abnormal pressure. The abdominal wall was decidedly rigid. I stopped his cathartics and let him eat liberally. After three rubbings he was much better; after seven rubbings he was well, his abdomen was soft and nothing abnormal could be made out about the colon. For two years he has been in excellent health except that from time to time he will be taken suddenly with fullness in the abdomen, vertigo, headache, and prostration. At such times the colon is always found distended with gas and the abdominal wall more or less tense. In half an hour after the rubbing the symptoms let up, the abdomen softens, and he passes a lot of flatus.

I do not believe his symptoms were due to absorption, but to a nervous reflex induced by a colon contracted and motionless over an increased content of gas.

Case VIII.—Colon contracted on gas with headache, simulating toxemia of pregnancy; cured. Woman thirty years old of costive habit. Three months pregnant for the first time. She has had a lot of nausea and has had to take cascara every night and even then her bowels move infrequently and with great difficulty. She is having abdominal pain and discomfort and sick headaches. Her face is drawn and she looks quite sick. The abdomen is a little enlarged, quite tender and markedly rigid. The percussion note indicates a colon containing somewhat too much gas under pressure. No splashing or rumbling and apparently no peristalsis is taking place.

Medicine was stopped and rubbing begun. The bowels moved next day; the rigidity was less and she felt better. At the fourth rubbing the abdomen was much softer, the colon less flatulent, the bowels moving regularly, and the headache gone. After nine rubbings she was relieved of all the above symptoms and suffered no return of them during her pregnancy.

True thickenings of the caput, probably chiefly due to perityphlitic adhesions, are not rare and do not feel quite the same as the gas tumors described above. Sometimes the thickened and palpable bowel is contracted into a banana or cord-like mass. Such caputs are not tender unless full of gas, but they seem to predispose to chronic constipation and other functional derangements, and seem to interfere with the success of rubbing. In two of the three failures to relieve constipation this condition was present, but, on the other hand, so it was in one of the most successful cases (Case V).

When a caput becomes flatulent, painful, or tender, with or without true thickening, the condition is often diagnosed subacute or chronic appendicitis. I have been able to cure several such cases promptly by rubbing. Others, however, with a true thickening can be relieved at the time but show a persistent tendency to recur, and in them I believe it probable that there is a real typlitis with exacerbations, probably involving the appendix as well.

Dilatation of the colon with relaxation of the muscular coat occurs and involves the ascending, the transverse, or even the whole length of the colon and can be usually recognized by splashing sounds on palpation as well as extensive areas of tympany. Such guts are met with in chronic constipation. Reflex head symptoms may occur with them, but they do not cause abdominal pain. When the condition is extreme it interferes seriously with the general health.

Case IX.—Dilated and relaxed colon. Woman thirty-nine years old. For eight years she has been constipated and now takes a cathartic every night. For five years she has had attacks of abdominal pain, diarrhea with mucus in the stools occurring three or four times a year and lasting about two days. She has abdominal discomfort and general lassitude much of the time. She has lost fourteen pounds in weight. The abdominal wall is soft. The caput, ascending and transverse colon, as shown by the enlarged tympanitic area and the extensive splashing sounds, are much enlarged, relaxed, and contain gas and fluid. Lavage shows the stomach to be neither enlarged nor inflamed. She was rubbed eighteen times; the bowel began to move regularly at once. The colon steadily diminished in size until it could no longer be made out at all enlarged.

It is well known that fecal masses may lodge in the colon, apparently in the sacculi, without occluding its lumen. They cause inflammation of its wall, resulting in localized pain and tenderness, and, in old people, nausea, vomiting, and diarrhea in addition. This condition merges into true diverticulitis, but the conditions amenable to massage are probably fecal accumulations in shallow pockets with wide mouths, not in the true flask-shaped diverticula. I have encountered these masses only in the transverse and descending colon. They may be removed by massage.

Case X.—Fecal mass on wall of colon; cured. Woman forty-five years old. Constipated since girlhood; takes as little cathartic as possible and often misses two or three days. For five months she has had pain in the left flank not severe, but enough to disturb her sleep. She is bothered by bloating and flatus. She is an usually robust woman. Her abdominal wall is muscular, but not tense. A firm, tender mass can be felt in the left flank, 2½ inches long, in the line of the descending colon. The rest of the colon is normal. The day after the first rubbing the bowels moved and the mass had almost disappeared; the next day it was gone for good. Her constipation was cured in twenty-two rubbings.

Fecal concretions of this kind on the colon wall may be very large and may remain for months and years, causing pain but not seriously interfering with the passage of feces through the bowel. If large, they cause very severe pain when finally passed.

CASE XI.—Large fecal concretion passed after two years. Woman sixty years old. For two years she had attacks of colic. I saw her in one and could make out no mass. Her abdomen was very large and hard to examine. Her bowels moved regularly with the assistance of occasional cathartics. At the end of this time (two years) she had an attack of obstinate constipation and abdominal pain. With cathartics and enemata she passed a lot of hard, dry, rounded fecal masses. One month later she was taken suddenly with a very severe colic and soon began to pass hard feces mixed with some mucus and much blood. This continued for several days, when she finally expelled a large round, hard mass nearly as large as her fist. After this she was well.

The passage of mucus with the stools is by no means infrequent in habitual constipation, but it is difficult to determine how much of it is due to the constipation and how much to the treatment. At all events, it regularly disappears under massage (see Case V). That the mucus can be produced by enemata and irrigations is beyond question (see Case II).

Some people have more or less continuous abdominal pain, sometimes localized, sometimes general, unassociated with constipation or any appreciable abnormality in the colon. Certain such cases can be cured by colon massage, the trouble being probably caused by irregular contractions of the muscular coat.

CASE XII.—Pain in the colon with no other disturbances; cured. Woman forty-five years old. Health always good and her bowels regular. For two weeks quite severe pain all through her abdomen and loins. Bowels move every day. Has taken no medicine. The abdomen is soft and natural. There is a little more gas than usual in the colon, but no evidence of any other abnormal condition. After seven rubbings the pain was gone and there was less gas in the colon. The same condition returned a year later and was again cured by the same plan.

Though convinced that the majority of head and general symptoms associated with these disorders of the colon are not produced by the absorption of poisons, a few cases have come under my care in which this factor seemed unquestionably present.

In conclusion, I may state my beliefs:

1. A considerable amount of fecal matter and an appreciable amount of gas are normal contents of the large intestine, and marked alteration in the quantity and character of its contents cause perversions of its normal function.

2. Pronounced departures from the normal activities of the muscular coat, either relaxation with dilatation or tonic contraction over increased contents, give rise to both subjective and objective symptoms.

3. Treatment should aim to restore the normal contents and activities of the colon rather than to keep it empty and overstimulate its muscles and glands.

4. Abdominal massage is an excellent means to this end when less cumbersome methods fail.

A NOTE UPON THE IODINE-PHOSPHORIC ACID REACTION IN THE URINE IN SYPHILIS.*

BY ROBERT A. KILDUFFE, A.M., M.D.,

PITTSBURGH, PA.

DIRECTOR, LABORATORIES, PITTSBURGH HOSPITAL; DIRECTOR, LABORATORIES, MCKEESPORT HOSPITAL; SEROLOGIST, PROVIDENCE HOSPITAL.

AMONG the numerous "short cuts" proposed for the diagnosis of syphilis is a urine reaction originated by Gray.[1]

Two reagents are required: A 10 per cent. solution of phosphoric acid and a solution of "resublimed iodine in chloroform or carbon tetrachloride."

In the series herewith reported the iodine was used as a saturated solution in chloroform because it was found that solutions of less concentration gave invariably "positive" results.

The urine, to be suitable for the test, must be fresh, with a specific gravity of less than 1.016, of acid reaction, and free from sugar. The presence of sugar, the recent ingestion of alcohol, or polyuria due to diuretics or the excessive ingestion of fluids all interfere with the test, so that the reaction is restricted to such cases as comply with the above restrictions.

The technic is as follows: To 6 c.c. of urine in a test tube add 1 c.c. of the iodine reagent and shake. The chloroform, after settling to the bottom, is either a pearly white (negative reaction) or pink or purple, which may be a positive reaction. If there is color in the chloroform layer, add 1 c.c. of the phosphoric acid solution and again shake. If the chloroform layer is decolorized the reaction is negative.

Gray, reporting the results obtained in a study of 200 cases comprising syphilis, normal controls, and a variety of medical and surgical conditions, found the reaction positive in all cases of syphilis tested (52), all cases also being Wassermann positive. With the exception of pneumonia, glycosuria, and polyuria, none of the other conditions, including the healthy controls, gave the test.

Because of these results and because, as noted by Klauder and Kolmer,[2] apparently the same reagents were placed on the market as a commercial preparation, it was thought of interest to try out the reaction in these laboratories.

The plan adopted was to make the test on every urine entering the laboratory which was found suitable, checking up the results by a blood Wassermann, and also to secure a specimen of urine, whenever possible, from every case in which a blood Wassermann was made.

The conditions investigated included cases of syphilis in varying stages, treated and untreated, and a variety of medical, surgical, and gynecological cases from the wards of the Pittsburgh Hospital, in addition to cases from the wards of the McKeesport Hospital and the genitourinary dispensary. A total of 352 urines was found available for the test.

The statements of Gray in regard to "positive"

*From the laboratories of the Pittsburgh and McKeesport hospitals.

reactions occurring in pneumonia, glycosuria, and tuberculosis were fully corroborated.

In the series tested there were 56 positive urine reactions, excluding the fallacious "positives." The Wassermann test was positive in 10 of these cases only, the serum being anticomplementary in one other. In the remaining 45 cases there was neither history, clinical signs, nor laboratory evidence of syphilis.

There were 32 cases of syphilis in the series, the Wassermann and history being positive. The urine reaction was negative (Wassermann four plus) in 19 and positive in 13.

Owing to the comparatively few specimens found suitable for the reaction and the discordant and unreliable results obtained, the investigation was not carried further.

Conclusion.—The urine reaction described is unreliable and valueless as a means of diagnosis in syphilis.

Medicolegal Notes.

Insufficient Evidence of Negligence in Diagnosis, Treatment, or Premature Discharge.—In an action for negligent treatment of an injured knee there were three specifications of negligence: Negligence in making a diagnosis that the injury was the result of a torn muscle and not a broken patella, as turned out to be the case; negligence in the treatment, and negligence in a premature discharge of the plaintiff as cured. The opinion of the court on these points, reversing a judgment for the plaintiffs, the patient and her husband, is as follows: "1. As to negligence in the diagnosis: The strongest point in the plaintiff's favor was the statement that there was an indentation on the knee that followed the break in the bone, and large enough to hold the finger. There was undisputed evidence, however, that a torn muscle would have produced the same depression. The evidence is all one way—that an injured knee presents difficulties of diagnosis that mislead the most skilful physicians. When Dr. Fuller (who subsequently took the case) was on the witness stand, he was asked: "Q. Would the average practising physician, who knows enough to practise, have had any difficulty in making a diagnosis? A. I do not know what the average man would be able to determine." That was the question as to negligence. The fact that the assistant of Dr. Fuller, who made a careful examination under the most favorable circumstances, did not believe the patella to be broken, negatives the charge of negligence in the diagnosis. When the testimony of the other witnesses, uncontradicted, is that mistake in the diagnosis of the injury to a knee is liable to occur with the most skilful, is added, then negligence in a diagnosis goes out of the case.

"2. As to negligence in treatment: All the doctors said that the figure 8 bandage (with which the defendant bound the knee) was a well-recognized method of treating this kind of injury, even where the patella was broken. It may be better to operate, but even operations are not always successful. There is no evidence from which negligence of treatment can be inferred.

"3. As to premature dismissal: The plaintiffs testified that the defendant told them that Mrs. Dillishaw was cured and could walk; that this statement was untrue, and she could not walk at all. The appellant denies this, and states that he quit the case when he learned that Dr. Fuller had been called in, and that is the proper practice. If this statement is material, the case should have been sent to the jury. It is not material. There is nothing in the case to show that they have done or refrained from doing anything to their injury on account of the untrue statement. The operation was not performed for months after they knew that the patella was broken. More than this, even if Dr. Bell did tell Mrs. Dillishaw that she was cured and could walk, she knew better than any one else that she could not walk a step and was not cured. There are some treacherous diseases, where visible manifestations disappear; but the skilled physician knows that the danger is not at an end. The ordinary mortal does not know it, and may be misled to his injury by a false statement. This is not such a case. No injury did or could have resulted from the false statement, even if it was made. Hence it is immaterial. A verdict should have been directed for the defendant, and the judgment appealed from is reversed."—Dillishaw v. Bell, S. C. Supreme Court, 105 S. E. 410.

Insufficient Evidence of Negligence in Setting Fractured Leg.—In an action against three physicians, charging negligence in setting and treating a compound fracture of the plaintiff's right leg "and in attempting to set and reduce the broken and fractured bones to their proper positions and place," it appeared that the injury was caused by the plaintiff's being thrown from a buggy, and the evidence showed that two hours elapsed before treatment could be given; that there was necessarily a certain amount of dirt and leaves which stuck to the bone, and that several pieces of loose bone remained in the plaintiff's leg. The other essential facts are stated in the opinion of the Missouri Court of Appeals, affirming a judgment for the defendants, as follows: "Not a single witness for the plaintiff, expert or otherwise, testified that the treatment of the injury by the defendants was done in a negligent or unskilled manner. The only question upon which it could be contended that there was any negligence shown was that the result of the injury and the treatment in and of itself showed an unskillful and negligent treatment, and the principal fact relied on in this respect is that some thirty days after the doctors had begun to treat the case, and after a serious infection had set up and pus was being emitted from the wound, a piece of leaf the size of a thumb nail came out. It is further shown that small slivers of bone came out of the wound from time to time. The testimony of the witnesses for both sides goes to show that an injury of this kind, where the bones break through the flesh and come in contact with leaves, dirt, and foreign substance, will in all probability cause an infection to set up, and that the proper treatment is to first treat the infection until it has been reduced and then treat the fracture. At no place in the record do we find any witness who testifies, stating that the treatment this plaintiff received was different from that which the ordinary physicians would have used in the case. On the other hand, it shows that in cases of this class infection is almost sure to set up, that they are very difficult fractures to properly cure and set, and that very often after the infection subsides the bones must be reset and treated. The evidence shows in this case that something like sixty to sixty-five days after this injury defendants told the plaintiff his leg should be rebroken and set properly, and that he told them he was not strong enough to stand this. This injury was very serious, and an unfortunate occurrence for this plaintiff, as he must go through the balance of his life with practically a useless limb; but there is a failure of proof in this record to show that his misfortune was added to by any negligence or unskillfulness of his physicians. To hold otherwise would base a finding on conjecture pure and simple. The trial court should have granted the demurrer to the evidence at the close of the case. For this reason the judgment will be affirmed."—Connelly v. Cone (Mo. App.), 224 S. W. 1011.

Contracts for Compensation—Capacity of Patient.—The Arkansas Supreme Court holds that where a patient, at the time of entering into an agreement with a physician as to compensation for the latter's services, was not of sufficient mental capacity, by reason of his illness, pneumonia, to transact business, the physician could recover only the reasonable value of his services, and not upon the express contract.—Butler v. Oldham (Ark.), 224 S. W. 985.

THE PROTECTION OF THE PATIENT IN SURGERY OF THE THYROID.

FOR many years Crile has insisted upon the value of what he has called anociassociation and the technique of its application, or anociation. Although these theories at first evoked but little enthusiasm among prominent surgeons, the principles which he enunciated have now been accepted more or less by the great majority of competent surgeons. Crile found that his results were much better when the patient was protected as far as possible from mental as well as physical traumata both before, during, and after operations. Hence, fear and other emotional disturbances are minimized by the use of preoperative narcotics which promote mental and bodily rest; in some cases harmless inhalations in small doses are administered at a stated time each day for some days prior to the actual administration of sufficient nitrous oxide to accomplish complete anesthetization, so that the patient does not realize that the time for operation has arrived; and in various other ways the patient is protected as far as possible from all which might tend to excite or alarm; while during operation the patient's nervous system is likewise protected from shock by nerve blocking, by the employment of nitrous oxide-oxygen anesthesia, and by rapid operation with sharp dissection and gentle handling of tissues. Crile has become convinced that the complete exclusion of both traumatic and emotional stimuli will wholly prevent the shock of surgical operations.

In no field of surgery are the beneficial results of the employment of the methods championed by him more clearly shown than in operations for toxic goiter. It seems almost unbelievable that a consecutive series, still unbroken, of 322 thyroidectomies and 139 ligations of thyroid vessels could be performed without a death; yet, under anociassociation, that is the record achieved by Crile and his confrères, according to his report in *Surgery, Gynecology and Obstetrics*. Of course not all of these goiters were of the toxic type, but a large percentage were. The elaboration of a preoperative, operative, and postoperative technique which made such results possible was based upon experimental researches and upon a clinical study of a personal series of 821 ligations and 2,771 thyroidectomies, 1,315 of the latter being for exophthalmic goiter.

What are the measures which have made such results possible? or, as Crile says, "Against what is the exophthalmic goiter patient to be protected?" He answers this by saying that he should be protected against the fatally excessive metabolism which the operation tends to induce, against failure of the already weakened myocardium, and against acidosis. "In brief," he says, "these patients must be guarded against psychic, traumatic, biochemical, and anesthetic stimuli; and, in addition, against the effects of the secretion of the thyroid itself. Whether the operation is to be performed with the patient in bed or in the operating room, on the day of operation he should see no surgeon, should see no preparation, should see no operating room, but should see only the already familiar anesthetist, the already familiar anesthetic apparatus; should experience only the already familiar odor of the gas and oxygen and the already familiar sensation of this type of anesthesia."

The patient operated upon must also be protected against suboxidation; and since all inhalation anesthetics cause suboxidation in extreme cases, deep surgical anesthesia, especially ether anesthesia, is ruled out. Crile considers that gas and oxygen anesthesia, combined with local anesthesia, is entirely free from this serious objection. He finds that a weak myocardium or a decompensated heart leads to serious suboxidation because of the diminished blood supply; and that against this condition the patient is best protected by one or two courses of digitalis, each consisting of 30 minims of the tincture every four hours for fifteen doses, repeated as may be required until edema disappears and the tone of the heart is as good as its condition will permit. Next, the patient must have plenty of water, by mouth if possible, otherwise, under local anesthesia, subcutaneously. The danger of too sudden withdrawal of thyroid secretion may be avoided by giving two grains of thyroid extract the night before and two grains on the morning of operation. The occasional necessity for serial operations (one or more ligations followed later by thyroidectomy) is emphasized. Among other measures are the preoperative narcotic, usually morphine and scopolamine; the protection of the patient from postoperative pain by the injection of quinine and urea hydrochloride; protection from excessive absorption of thyroid secretion by proper drainage, even to the extent, if necessary, of leaving the wound entirely open temporarily; and the reduction of excessive temperature by a sufficient number of ice bags or the ice pack.

ARSENIC IN MODERN THERAPEUTICS.

ARSENIC is a normal component element of the human organism, retained in the structures in correlation with cutaneous functions and organs of reproduction. The leucocytes are the agents of elaboration and assimilation of arsenic normally

ingested with food or for therapeutic purposes. The skin and its adnexa and the menses are the natural routes for its elimination. The excess of arsenic is eliminated in the urine in the form of an organic combination, and this elimination is already manifest fifteen minutes after the ingestion of sodium methylarsenate and lasts for a month, although 66 per cent. of the drug is eliminated in the first twenty-four hours. It does not appear that a fundamental distinction need be made between medication by mineral and that by organic arsenic, the ultimate action of the active products being essentially identical in both. Arsenic acts on the general nutrition like a ferment; that is to say, it does not create new energy, therefore is not dynamogenous, but it directs the already existing potential energy and realizes the maximum utilization of the reserves of the organism according to the manner of reaction of the living being in its defense against pathological processes.

Its action is first made manifest by an increase of the body-weight, stimulation of the appetite, return of strength, and a rapid and progressive amelioration of the patient's general condition. Arsenic causes the maximum of oxidation of organic waste products and tends to regulate the respiratory exchanges, at the same time decreasing the frequency of respiration. It lowers the temperature slowly and progressively in cases of mild fever and causes a temporary diminution in the total amount of urine, although without any untoward action on the kidneys. The arsenical preparations—especially the organic products—increase the number of red blood corpuscles with great rapidity, and this continues for a time after withdrawal of the drug. The percentage of hemoglobin also progressively increases.

As arsenic can be eliminated only very slowly a certain amount must accumulate in the body, and after a variable lapse of time, it will set up symptoms of intolerance preceding those of true intoxication. The organic preparations themselves, if given for a long time, are not entirely innocent of causing these accidents. Hence the practical indication to exhibit the drug in progressively increasing doses with intervals of rest, these doses always being calculated upon the content of the product in arsenic. In the case of the organic preparations the therapeutic doses average between two and ten centigrams. The hypodermic administration is always to be preferred, especially for the exhibition of the cacodylic compounds.

Generally speaking, arsenic is indicated in every case where it is necessary to raise the energy of the organism progressively and regulate the cellular nutrition. In pulmonary tuberculosis arsenic is particularly indicated in the prolonged torpid forms, in which case it acts as a tonic and not as an antimicrobic agent. It is also useful in other varieties of human tuberculosis and in subjects with adenoids. In diseases of the respiratory tract other than tuberculosis, except for its general stimulating action, the effectiveness of arsenic is debatable. Although of value in the treatment of chorea, arsenical medication is not a specific; it is likewise useful in other neuroses, such as neurasthenia and Basedow's disease. Arsenic is indicated in all forms of anemia, especially associated with iron. It is absolutely indispensable in cases of severe anemia and in the progressive pernicious anemias. Its action is certain in the varieties of the lymphogenous diathesis, but the medication must be persevered in in order to maintain the good results obtained. Finally arsenical medication is excellent in the cachexia of malaria, but in the other infectious diseases—syphilis excepted—the action of arsenic is not clear. In diabetes, arsenic decreases the amount of sugar in the urine as well as other normal or abnormal fixed matter contained in it, and hence exerts a real effectiveness in phosphatic diabetes and the phosphaturia of rickets. Internally, arsenical preparations give good results in certain dermatoses, notably lichen planus, psoriasis, and the various forms of dry eczema. In syphilis arsenic controls denutrition, while combined with mercury its toxicity seems to be lessened.

The chief contraindications to the use of arsenic are hepatic insufficiency and the diarrhea of tuberculosis. The organic preparations of the drug should be carefully watched in cardiac subjects or those presenting a tendency to congestion or to pulmonary or intestinal hemorrhage.

POSSIBLE ROLE OF THE HELMINTHS IN THE CAUSATION OF RAT CANCER.

A DISCUSSION of the part played by certain worms in the etiology of cancer is limited in ordinary literature to the experimental work of Fibiger of Denmark and the conditions under which the experiments were made were highly artificial. The rat was the animal concerned and the parasite had the cockroach for a host. When the animals ate the insects in question they were said to have developed cancer of the stomach with metastases. But these were not the earliest experiments along this line (Joyeux, *La Presse Médicale* for June 1, 1921, xxix, 48), for Borrel had previously shown that the cat tapeworm may cause malignant tumors in the livers of rats. Fibiger's cancerogenic worm is a nematode which has become known as the *Spiroptera neoplastica*. The use of an insect host, which serves to complicate the experiment, is not absolutely necessary, but in order to obtain the parasite in its larval state the passage through such a host is very convenient. While the so-called bakery cockroach was used, other insects may also answer. The roaches obtain the parasite through feeding on the dejecta of the rats and mice of the bakery and hence are very convenient as a reservoir of the worm. The rats in turn devour the insects. The pied rat of the laboratory is very easily

infected by eating the roach of the bakeries—much more so, apparently, than the wild rat of the bakery.

The lesion is usually set up in the cardia, where the worm is apt to lodge, and is a fibroepithelioma of decided malignancy, which may perforate the gastric wall and set up purulent peritonitis. The worms which exceptionally are fixed at the base of the tongue are known to cause a glossitis and sometimes cancer of the tongue, which agrees with the form seen in mankind. Metastases of these growths may be limited to the regional lymphnodes or may appear in the lungs as well. Fibiger has also been able to inoculate other rats with these tumors. The metastatic nodes are free from worms, which certifies that not the worm itself but some unknown *x* is the efficient cause of the neoplasm. In fact, even in the parent growth they are to be seen only at the outset. They are known to succumb and vanish utterly, while the cancer pursues its evolution without their aid. Clearly the *materies morbi* is some product of the worm but what is as yet unknown. It is rather singular that only one species of these nematodes is able to produce rat cancer. The animal harbors a number of other nematodes which are quite innocuous and at the same time the pied laboratory rat shows a much greater susceptibility than any of the free rodents. Perhaps his captivity has caused a constitutional change analogous to that which civilization produces in man whereby he acquires a tendency to the cancer disease. This brings to mind the factors of highly individualized irritants and highly specialized soil in cancer genesis. Something analogous is seen in tar cancer of mice in which the tar is a special irritant and the white mouse the special victim: and, by the way, the latter is highly refractory to infection by the *Spiroptera*. Man does not harbor this particular worm but neither does he suffer from the so-called cancer of lower animals. Primitive peoples, said to be almost immune to cancer, certainly harbor nematodes of various kinds; so that as far as worms are concerned they have evidently played no rôle, or at most a very indirect one by affecting metabolism, in the evolution of human cancer.

Symptoms of Syringobulbomyelia Mistaken for Acromegaly.

That a felon may mask the existence of the disease syringomyelia has long been recognized, but the latter affection does not usually require differentiation from acromegaly with associated mental disease as in a case reported by Benon and Daveau in the *Gazette des Hôpitaux* for May 3-5, 1921, xciv., 35. The patient, a man of twenty-six and ex-soldier, was referred to a psychiatric service for mental symptoms and with the presumptive diagnosis of acromegalic deformity of the head and hands. He was of sound stock and had never been ill. The first symptom had been noted four years before—a felon of the painless type which opened spontaneously. Its seat was the left medius. The affected finger and other digits were hypertrophied, hard and livid, and as a suppurating ulcer had formed the member was amputated with the diagnosis of *spina ventosa*. Four years later, on admission into the psychiatric service, he presented numerous symptoms. There were muscular atrophy of the left hand, thinning of the forearm, and suggestion of atrophy in the shoulder muscles. In the opposite extremity conditions were parallel, although the hand was not so far atrophied. The lower extremities were almost normal, although there were evidences of a beginning radicular amyotrophy. The tongue showed atrophy, especially to the right. There was an abundance of evidence to justify the diagnosis of syringobulbomyelia. The mental state was one of slight primary debility affecting the memory and judgment, which was puerile. There had been no progressive or secondary mental impairment. The hypertrophy of the digits and hands was of the acromegalic type and there was dorsal and high shoulder scoliosis. This, in association with overdevelopment of the cranial vault, had been responsible for the diagnosis of acromegaly with secondary involvement of the mental functions.

The Surgical Treatment of Pulmonary Tuberculosis.

The relative silence of medical periodicals on this subject since the beginning of the World War in 1914, has doubtless given rise to the belief that artificial pneumothorax has not been holding its own in three years. Such an opinion is possibly premature. Dr. Carlos Jaeger, who has recently sojourned at Munich, at Sauerbruch's surgical clinic, has contributed a very interesting article on the subject to the *Revista Española de Medicina y Cirugia* for April, 1921, iv, 34. After a brief historical outline of thoracic surgery, the author leads off with artificial pneumothorax which he terms the Forlanini-Saugmann operation, making no mention of the revolutionary work of Murphy in this field. The name of Saugmann is interjected because of the cannula which he devised in this connection. The combination of this operation with sanatorium life in Alpine stations has given Sauerbruch permanent recoveries in 68.5 per cent. of cases treated. The author gives an account of the operations of Brauer-Friedrich and Wilms, but it does not appear that Sauerbruch has made any use of them, as his own procedure was sharply individualized before the war, and he already was far in the lead of his competitors in operations and results. Despite some obscurity on the part of the author we understand that the figures to be quoted refer entirely to the Sauerbruch operation. The total has considerably more than doubled the figures published before the war, and now amounts to nearly 400 cases (381). Of this number of patients no less than 134 are said to have recovered, which amounts to 35 per cent. The mortality during the first few postoperative days was 2 per cent. and during the entire postoperative period 12 per cent.

Amblyopia ex Abusu.

This clinical entity owes its existence largely to the fact that its victims are almost always addicts of both alcohol and tobacco. The patient complains of inability to "see off." Paradoxically

he sees better when illumination is poor, often best at twilight. Thus his visual disturbances have a hemeralopic component. In cases with central scotoma this improvement at twilight is not paradoxical, for the coming of sundown causes pupillary dilatation just as the noon sun causes miosis. There is a curious inability to tell the colors of small objects, especially when green or red is concerned. The victim also makes mistakes in changing coins. Often these visual troubles are associated with psychic alterations, so that confusion may arise in the mind of the medical man. Ophthalmoscopic finds are usually negative, although there may be a paling out of the optic disk. Naturally we have to exclude the possibility of methyl alcohol poisoning and the ophthalmoscope enables us to make this distinction since the latter intoxication is attended by rapidly supervening atrophy of the optic nerve. Of prime diagnostic and therapeutic value in amblyopia ex abusu, according to Terson (*La Presse Médicale*, May 21, 1921, xxix., 41), is abstinence from alcohol and tobacco, which is usually followed by prompt return of normal vision. The teetotalist Turk suffers from simple tobacco amblyopia. Generally speaking, alcohol amblyopia occurs often when least suspected. The author has seen cases in drinkers of cologne water and tooth washes who were presumably abstainers. In fact pure alcoholic amblyopia (without coincident tobacco addiction) is apt to occur in the secret or innocent drinker, as in the case of a youth whose fond aunt stuffed him with wines and dainties. In such cases the odor of the breath may be decisive. Curiously the frank drunkard often escapes, while the man who drinks and stays sober suffers. Here it seems to be the cumulative action of the small but ever repeated dose which determines the result.

News of the Week.

Smallpox in State Hospital.—Discovery of ten cases of smallpox at the State Hospital for the Insane at Waterbury, Vt., was announced by officials of the institution on August 8. The disease was brought to the institution by a new patient. The infected persons have been isolated and the hospital put under quarantine.

German Physicians Boycott Allied Commission.—In Oppeln a German physician considered that he had been insulted by a French officer a few weeks ago, and accordingly arranged with his confrères to boycott the Allied Commission. After a time he relented so far as to consent to attend British and Italian members of the Commission, but continued, and still continues to refuse to attend a Frenchman. In the circumstances, the French have been obliged to employ doctors from Lower Silesia and Breslau. The Upper Silesian Union quickly took action, and now the Lower Silesian Union has issued orders that members are to support the Oppeln boycott of the French.

Medical Staff of Berlin Hospital Strikes.—It is reported that all the members of the medical staff of the Charité Hospital of Berlin have gone out on strike for higher salaries. About 160 Berlin physicians and surgeons are involved in it.

Hospital Notes.—Ground has been broken and work started on the erection of the new $200,000 wing to the Good Samaritan Hospital in Portland, Ore. A feature of the new wing will be the Clark memorial, which will have six main operating rooms, all thoroughly equipped.

Plans are being prepared for a new $2,000,000 city hospital on Walton Avenue, between 166th and 167th streets in the Bronx, New York. The building will contain accommodations for 500 patients, and it is expected that it will be ready for occupancy by the spring of 1922.

The Jewish Memorial Hospital, now housed in the former home of the Magdalen Benevolent Society of Dyckman-on-the-Hudson, has purchased additional plots of ground, 80 by 115 feet and 136.7 by 100 feet, at the northeast corner of Dyckman Street and Bolton Road.

A new $100,000 hospital at Pasco, Wash., built by the Sisters of St. Joseph, was opened for the reception of patients on July 30. The new institution will be formally dedicated in September.

The Speedway Hospital in Chicago, erected at a cost of $10,000,000, and which Mr. Edward Hines has donated to the Government in memory of his son, who fell in France, received its first quota of war veterans on August 8. Disabled soldiers will be transferred there from other hospitals.

Protection for Vacationists.—A communication from Dr. Edward Goodwin, sanitary supervisor of the Jewish Agricultural and Industrial Aid Society, has succeeded in organizing what is known as the Farmers' Sanitary League, in the district around Ellenville, N. Y. In order to obtain membership in the league a farmer or boarding house keeper must subscribe to and rigidly observe a sanitary code regulating sewage, garbage and refuse disposal, and laying down rules for fly prevention and a pure water supply. The code must be posted in a conspicuous place in the farmhouse, and periodic inspections are made by Dr. Goodwin to insure compliance with this self-imposed code, and to give advice and counsel on all problems relating to healthful conditions on farms. The officers of the New York State Health Department have co-operated with this activity. Every farmer who complies with all the requirements of the sanitary code receives a certificate good for a period of one year. This movement is commendable not merely because it makes a country locality more healthful, but because it gives assurance to the great army of vacationists that they have protection from communicable diseases in such communities.

Twins Total Twenty-eight Ounces.—Local doctors believe that Billie and Jack Adams of Bogalusa, La., are the smallest living babies. At birth Billie weighed eleven ounces and Jack seventeen. The midgets appear to be in perfect health. Six brothers and sisters are of normal size.

New Milk Regulation.—At a meeting of the New York City Board of Health, held July 25, 1921, resolutions were adopted amending Regulation 5, governing the production, transportation, and distribution of milk, to read: "No milk or milk products shall be graded or designated in a manner hereinbefore provided in these regulations until the source of supply of such milk or milk products shall have been, in each instance, approved by the Board of Health and graded and

designated in accordance with such approval. No person shall bring into the City of New York any milk or milk products, nor shall any person have, keep, sell or offer for sale at any place in the City of New York any milk or milk products, the source of supply of which has not been approved by the Board of Health.

Post-Graduate Course for Ship Doctors.—The Broad Street Hospital, New York, announces that it will open a Graduate School of Medicine on October 15, 1921. One of the chief features of the new school will be a course in tropical diseases, under the direction of Dr. Charles E. Sibley, who has had eight years experience with tropical diseases in the Philippines. The Broad Street Hospital is located near the docks and receives a goodly number of cases of malaria, typhus fever, and other tropical diseases. Special facilities are also offered in other lines of medicine and surgery. Each course will last one month and will be repeated indefinitely, so that a ship's doctor who is in town for a week can take a part of his course and drop in again when he is in New York to continue it. The officers of the Graduate School are: Director, Dr. A. J. Barker-Savage; president, Dr. W. H. Dieffenbach; first vice-president, Dr. Robert T. Morris; second vice-president, Dr. Lefferts A. McClelland; third vice-president, Dr. Walter Gray Crump; secretary, Dr. Maximilian Stern.

To Dedicate the Medical College in Pekin.—John D. Rockefeller, Jr., Dr. George E. Vincent, president of the Rockefeller Foundation, and Dr. William H. Welch of Johns Hopkins University have started for China to attend the dedication of the buildings of the Pekin Union Medical College, erected by the China Medical Board of the Rockefeller Foundation. They sailed from Vancouver, where they were joined by a party of distinguished medical men and educators, on August 18.

Dr. Irving D. Metzger of Pittsburgh has been elected chairman of the State Bureau of Medical Education and Licensure to succeed Dr. J. M. Baldy, who has been appointed Commissioner of Welfare.

Dr. Charles W. Selover of Canandaigua, N. Y., has been appointed superintendent of the Ontario County Tuberculosis Hospital, in the place of Dr. William A. Bing, resigned.

Dr. Francis O'Brien has been appointed superintendent of the Hampshire County Tuberculosis Sanatorium at Leeds, Mass., to succeed Dr. Charles E. Perry, who resigned recently to take charge of a government tuberculosis hospital in California.

Dr. P. H. Aaser, director of the Norwegian State Hygienic Laboratories, Christiania, is visiting prominent laboratories in the United States for the purpose of studying their organization, equipment and functions.

Dr. Murayama of Japan is visiting laboratories and hospitals in this country.

Dr. W. H. McGregor of Wilkinsburg, Pa., is the Republican nominee for coroner of Allegheny County.

Dr. E. William Abrahamowitz has removed his office to 235 West Seventy-first Street, New York City.

Jury Acquits Doctor.—Dr. Fred VanVliet of New York, who was tried before Judge Rosalsky on a charge of having attempted an illegal operation, was acquitted on Aug. 12. The jury expressed its disapproval of the police method of obtaining supposed evidence against Dr. VanVliet.

United States Public Health Service Training School for Nurses.—A training school for nurses of the U. S. Public Health Service is to be established by the Surgeon General which will offer to women desiring to take up the profession of nursing a three years course of study leading to a diploma and an opportunity to assist in caring for disabled military patients. The headquarters of the school is in the office of the Surgeon General, Washington, D. C. Training will be given in certain hospitals in the service. Schools will open on Sept. 1 at Fort McHenry in Baltimore and at Fox Hills, Staten Island, N. Y. The service hospitals provide experience in surgical nursing, including orthopedic, eye, nose and throat; medical, including communicable, nervous, and mental diseases; *x*-ray and laboratory technique; experience in the diseases of children, and public health nursing. Gynecology and obstetrics will be provided in the second or third year of the course through affiliations with civilian hospitals. No tuition fee is required and a monthly allowance of $30 is provided during the first two years and $50 during the third year. Candidates should make application in person or writing, to the Surgeon General, U. S. Public Health Service, Washington, D. C. Special consideration will be given to candidates who have taken the course in Elementary Hygiene and Home Care of the Sick with the Red Cross or who served as nurses and aides in army or civilian hospitals throughout the war. Candidates must be between 21 and 35 years of age, must pass satisfactory physical examination, and must be graduates of a recognized high school or present evidence of an educational equivalent.

An Appeal for Help by Bronx Physicians.—The group of medical practitioners of Bronx Borough of this city, constituting the newly organized Bronx Physicians' Club, are seeking assistance to enable them to erect a building, to be called the Bronx Academy of Medicine, at a cost of half a million dollars. The building will contain a library, a laboratory, room for medical meetings, an auditorium for public lectures on medical subjects, a gymnasium, swimming pool, bowling alley, restaurant, tennis court, nurses' room, and rest rooms. In order to obtain funds for carrying out this ambitious project it is proposed to have a bazaar on October 15-22, to seek donations from philanthropic laymen, and also to ask every physician in this and neighboring States to contribute at least $1 each. The committee soliciting donations consists of Drs. Isaac Rich, chairman, B. A. Kantrowitz, vice-chairman, and G. A. Rueck, secretary.

Joint Meeting of Medical Associations.—The following medical associations will hold a joint meeting in Kansas City, Mo., beginning Monday, October 24: Medical Veterans of the World War; Medical Society of the Missouri Valley; Medical Association of the Southwest; Mid-Western Association of Anesthetists; Central States Orthopedic Club; Southwestern Branch, American Urological

Association. The medical societies in Kansas City have united to furnish an ample clinical program for the mornings and the afternoons will be occupied with scientific sessions.

Obituary Notes.—Dr. CHARLES R. MAHADY R. Rome, N. Y., a graduate of the Baltimore Medical College in 1897, and for thirteen years health officer of Rome, died on August 8, at the age of forty-nine years.

Dr. SANDERS R. TOOMBS, formerly professor of clinical medicine at the University of Tennessee, Nashville, died in Lexington, Ky., on July 15, at the age of seventy-seven years. He was for seventeen years president of the Mississippi State Board of Health.

Dr. FRANK H. TODD, a graduate of the Western Reserve University School of Medicine in 1876, died at his home in Cleveland, Ohio, on July 17, at the age of seventy-two years.

Dr. WILLIAM E. DOWNIE of Minneapolis, a graduate of the University of Louisville Medical Department in 1912, died suddenly on July 21 at the age of thirty-seven years.

Dr. FRANK HURLOCK of Philadelphia, a graduate of Jefferson Medical College in 1881, died at his home on July 24 at the age of sixty-two years.

Dr. WILLIAM B. COGSWELL of Stratford, Conn., a graduate of Bellevue Hospital Medical College in 1881, died on July 28 at the age of sixty-six years.

Captain GEORGE A. LUNG, medical officer at the Naval War College at Newport, died suddenly on July 26 at the age of fifty-nine years. He was graduated from the University of Pennsylvania School of Medicine in 1886. He entered the Navy as assistant surgeon in 1888 and was made surgeon in 1900. He served with Samson's squadron at Santiago and in many capacities both ashore and afloat.

Dr. WILLIAM H. COX, a retired physician of Sandy Creek and Syracuse, N. Y., died at Sandy Creek on July 18 at the age of eighty-two years. He was a Civil War veteran.

Dr. GEORGE DE FOREST SMITH, formerly of New York City, died at his home in Kingston, N. Y., July 30, at the age of sixty-nine years. He was graduated from the College of Physicians and Surgeons, New York, in 1876. He was a member of the New York Academy of Medicine.

Dr. CLOVIS ADAM of Jersey City, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1877, died at his home on July 28. He was formerly connected with the staffs of the French Hospital, the Manhattan Eye, Ear, Nose and Throat Hospital and the Orthopedic Hospital in New York City.

Dr. SAMUEL C. SIMS of Memphis, Tenn., died after a lingering illness on July 14 at the age of fifty-nine years. He was graduated from the Vanderbilt University Medical Department, Nashville, Tenn., in 1893.

Dr. FREDERICK W. LAKE, a graduate of the University of Pennsylvania Department of Medicine in 1901, died at his home in Omaha, Neb., July 10, at the age of forty-five years.

Dr. JEFFERSON DAVIS FENTON of Portland, Ore., a graduate of the University of Oregon Medical School in 1889, died suddenly about March 19.

Dr. CHRISTOPHER DEAN MOWRY of Aurora, Ill., a graduate of Rush Medical College in 1876, died in a local hospital on July 6 at the age of seventy-five years.

Dr. HOWARD A. FEHR, a graduate of Hahnemann Medical College and Hospital, Philadelphia, in 1894, died of nephritis at his home in Allentown, Pa., on July 16, at the age of fifty-one years. He was a former president of the Lehigh Medical Society.

Dr. H. N. GRAVES, a retired practitioner of Dallas, Tex., died on June 23 at the age of seventy-five years. He formerly practised medicine at Gonzales, Seguin and Georgetown.

Dr. EDWIN R. SMILEY of Philadelphia, a graduate of Jefferson Medical College in 1881, died after a lingering illness on July 19 at the age of sixty-one years. He served as coroner of Camden County, N. J., from 1890 to 1893, and was chief clerk and deputy coroner of Philadelphia from 1906 to 1909.

Dr. FREDERICK N. BEARDSLEE, a graduate of the Boston University School of Medicine, formerly assistant physician of the Norwich, Conn., State Hospital, and more recently practising in Manchester, N. H., died at Rye, N. Y., July 22, at the age of forty-six years. During the World War he was surgeon on an ocean liner and later had charge of a section engaged in fighting typhoid fever in Serbia.

Dr. ROBERT SELDEN of Catskill, N. Y., a graduate of the Western Reserve Medical College in 1869, died in a hospital in Troy, N. Y., July 23.

Dr. WILLETT SPURGEON CONNORS of Boston, Mass., a graduate of Dartmouth Medical College in 1891, died on July 31, at the age of fifty-two years. He formerly practised medicine in Brooklyn.

Dr. MARY ELIZABETH H. SHIPP of Salt Lake City, Utah, licensed to practise medicine in 1894, died on July 23, at the age of sixty-eight years.

Dr. MARTIN G. MEEHAN, a graduate of Rush Medical College in 1885, died at his home in Chicago on July 25, at the age of seventy years.

Dr. MARY ANN MCCAY of Sunbury, Pa., died in a local hospital on July 26, at the age of sixty-four years. She was graduated from the Woman's Medical College, Philadelphia, in 1887.

Dr. FLORENCE HALE ABBOTT, formerly of Newton, Mass., died in a Brookline hospital on August 1, at the age of fifty-four years. She was graduated from the Woman's Medical College of the New York Infirmary in 1891. She was a member of the American Medical Association, the New England Society of Psychiatry, and the American Medico-Psychological Association.

Dr. ALONZO M. MORRISON of Louisville, Ky., died in a local hospital on July 31, at the age of eighty-three years. He was a graduate of the University of Louisville Medical College in 1859, and served as a surgeon in the Union Army during the Civil War.

Dr. JOHN F. CROSTON of Haverhill, Mass., a graduate of New York University Medical College in 1881, died of heart disease on July 30, at the age of sixty-six years.

Dr. WILLIAM B. COGGSWELL of Stratford, Conn., a graduate of Bellevue Hospital Medical College in 1881, died in a Bridgeport hospital on July 28, at the age of sixty-seven years.

Dr. JOSEPH ALPHONSE LORRAINE, a graduate of the Montreal School of Medicine and Surgery in

1896, died on July 26 at the age of forty-eight years. He served in France as officer in charge of the radiological service of the Laval medical unit, and since the war had occupied the position of chief of the radiological clinics at the Bruchesi Institute.

Dr. DAVID DANDIE BROUGH of Boston, Mass., a graduate of Harvard Medical School in 1893, and formerly city Deputy Health Commissioner, died suddenly July 31, at the age of fifty-five years.

Dr. EDWIN W. MOORE, a retired physician of Franklin, Pa., died in the Memorial Hospital, New York, July 31, at the age of seventy-three years. He was a graduate of the Charity Hospital Medical College, Cleveland, in 1867.

Dr. ELLEN WOODWARD HOWELL, formerly of Middletown, N. Y., died in Philadelphia on June 7, at the age of fifty-three years. She was graduated from the New York Medical College and Hospital in 1892, and was recently connected with the staff of the Women's Southern Homeopathic Hospital.

Dr. LEONARD O. BUZZELL of Standish, Ore., a graduate of Dartmouth Medical School in 1882, died June 6, at the age of sixty-one years.

Dr. JAMES M. SLIGH, a graduate of the Detroit College of Medicine in 1881, died in Long Beach, Cal., on June 8, at the age of seventy-six years. He formerly practised medicine in Grand Rapids, Mich., and later in Anaconda, Mont., serving in the Montana Senate for several years. He was aide to General George E. Thomas in the Civil War.

Dr. NELLIS CLEMENT SATTERLEE of Williamfield, Pa., a graduate of the New York University School in 1889, died of carcinoma of the liver on May 15, at the age of fifty years.

Dr. THOMAS L. F. ARMITAGE of Princeton, Minn., a graduate of the Medico-Chirurgical College, Philadelphia, in 1893, died on June 3, at the age of fifty-nine years.

Correspondence.

TREATMENT OF FRACTURES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the issue of THE MEDICAL RECORD of July 9 appears an article from Dr. Ethan H. Smith on the treatment of fractures. It is a very readable article, but I take exception to some portions. In regard to plaster-of-paris bandages, preparing one's own is the only way to have them right. I failed to get the results Dr. Smith claims to have had with absorbent cotton. I have used everything that came out, beginning with ordinary cotton batting, then sheet wadding, then absorbent cotton, and finally I have used stockinette; this I find is the best. Have the surface washed clean with hot soap and water then, after drying apply sterile petrolatum, then the stockinette. After the plaster has set I divide on both sides so the top can be lifted off. This permits the inspection of the limb and one can note if anything is going wrong. One reason so many get such bad results from the use of plaster is that they are content with the bandages obtained from the drug store; then they leave the plaster on for days and weeks before it is opened, and they wonder why they fail and do not get union. In over five decades, where I have had the case from the start, I have not had a failure to get union and serviceable limbs. Dr. Smith objects to the use of anesthetics in the reduction of fractures. I have found that when they were used the muscles were relaxed and one did not have that involuntary contraction and resistance. His objection is there will be unnecessary manipulations. If one has not the tactus eruditus he should let such cases alone. In his treatment of fractures of the hip, he hangs on to that relic of the Spanish Inquisition, the sand bag, large and heavy. If he can handle them he does better than the most of us. I have used them in the days gone by and I now wish to forget it. For many years I have used a modification of the Hodgen splint as recommended by Dr. George S. Brown of Birmingham, Ala. With this and a wire splint that will fit around and grasp the joint the limb is swung up and the patient left happy. Dr. Smith especially condemns the use of anesthetics in the reduction of a Colles' fracture. I have been in out of the way places where I had to reduce them without anesthetics and I know it is painful in the extreme, besides making it more difficult.

Then Dr. Smith extends the plaster from the hands to the axilla, and leaves it on for four weeks, without removing it. The only thing he recommends is to cut it along the back. Why he carries the plaster to the axilla is beyond my comprehension; if that is correct I have, for fifty odd years, been treating my patients wrongly. The way I do is to use an anesthetic, then when the patient is perfectly relaxed reduce the fracture. The only way you can unlock the fragment is by grasping the injured forearm with the corresponding hand, then grasp the other above the fracture, and swing it up to right angle, this unlocks the fragments; then as you bring it down with a twist to the ulnar side you dislodge and restore the tendon of the extensor carpi ulnaris. When you have executed this let go the hand, and if it stays in place you are all right. Then apply the stockinette from the fingers to above the elbow, and apply the plaster roller. Begin around the wrist. Have one assistant hold the arm, another grasp the thumb with one hand, the ends of the fingers with the other, and hold firmly. In applying the plaster I begin around the wrist, carry it around the hand to the base of the fingers, then back up to the elbow. Put on about five layers, then after smoothing it, take it in your own hands, pressing the thenar eminence of the corresponding hand into the concavity above the upper end of the radius while the other presses on the posterior surface; thus you mould and make a perfect fit at the point of fracture. Then as soon as it is set, divide around the thumb and half of the thenar eminence, trim along the fingers so they can be flexed, then divide along on both sides. This enables one to lift off the top and inspect the condition, sponge and apply alcohol, and massage gently the exposed portion. This should be done every day; at the end of a week one should remove the splint, give the limb a hot bath, massage it, and feel the joint.

At the end of the second week we should begin manipulation, and at the end, of at longest, five weeks take off all and permit gentle motion. Have the patient bathe the arm three times daily, fol-

lowed by cold saline shower. I have no trouble in getting results that the patient is ashamed to show. Why Dr. Smith wants to keep the elbow flexed and inactive so long I cannot understand, as the only thing he gains is a joint that will annoy the patient as he tries to get it working again. With the elbow so it can be flexed and extended I have no trouble.

In fractures of the leg Dr. Smith says flex the leg if you want to relax the muscles. If he will divide the tendo Achillis he won't have any trouble, as that puts out of commission the muscles of the calf, and then if one has finger sense the fragments can be put in place without skidding.

The *x*-ray is all right but if you can't make out the average fracture without it you had better leave the job to some one else. Where you need the *x*-ray is after you have put it up, then see if you have it right.

These remarks are the result of the worry and experience of many years. A ready to fit splint is like the ready-made shirt, and gives as good satisfaction.

GEO. F. BEASLEY, M. D.

LAFAYETTE, IND.

CONFIRMATION REPUDIATED.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Emulating the politeness of your correspondent, Dr. Ernest S. Bishop, in his little letter of eight lines published in the MEDICAL RECORD, August 6, 1921, thanking me for my support and confirmation (*sic!*) of statements previously made by him, kindly permit me to express my sincere gratitude to Dr. Bishop for thus furnishing to your columns the most concise and clean-cut example one could possibly desire to illustrate what is meant by propaganda of the misleading type. Dr. Bishop therein "kindly and ably, though perhaps unconsciously," makes a valuable contribution to our knowledge of the gentle art of propaganda, conveying an entirely erroneous impression to persons unfamiliar with the facts.

J. MILTON MABBOTT, M.D.

19 FIFTH AVENUE,
NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 18, 1921.

Factors Bearing on Infant Mortality.—Among the many good papers read at the conference on Infant Welfare held recently in London that of Dr. C. W. Saleeby was one of the best. He pointed out that the outstanding fact of infant mortality during the past ten years in Great Britain was the suppression of infant diarrhea. He described the theory that infant mortality is an illustration of natural selection as baseless, completely breaking down even in the one instance, hemophilia, which might be expected to illustrate it, and he considered in turn the genetic, toxigenetic, gestational, and obstetric factors of the problem. Mr. James Stewart of Glasgow contended that many difficulties did not arise through ignorance, but purely and simply owing to social conditions, and until such conditions were adequately ameliorated and every mother had all that was necessary for the well-being and comfort of herself and her child, there would be no good done, even though they held conferences to eternity. Dr. Wynne thought that the more successful they were in their endeavors in reducing infant mortality the more seriously would they have to contemplate what steps they were to take toward reducing the unregulated begetting of unwanted children. Dr. Saleeby, in replying to points raised in the discussion, observed that drinking among young mothers was a peculiarity of Great Britain. As for improvement in social conditions there was nothing more tragic than a mother doing her maternal duty and breast feeding her baby when she herself was badly nourished. The first charge on the state ought to be the mothers and children of the country. Another paper of great interest was that of Dr. H. Kenwood, M. O. H., Stoke Newington, who said that in public health generally the real need of the hour was for more knowledge of the very simple laws of health. Whatever the baby was fed on the parents must also receive the mental pabulum, rendered easily assimilable, peptonized and humanized. In maternity and child welfare work, extended to the school age and followed by medical inspection among school children, they had a guarantee, given reasonably good economic conditions, of an early reduction in the proportion of the C 3 population.

Physical Education in the Universities of the United States.—At a meeting of the Edinburgh Medico-Chirurgical Society, held on July 6 last, Prof. Tait Mackenzie of the University of Pennsylvania described physical education as conducted in the American universities. With regard to the educational part of the course, it was pointed out that exercises correcting the effects of a sedentary life were prescribed. Games designed to occupy many men in a short time were organized and every attempt was made to foster that physical intelligence which had raised man above the brutes. The student was taught the benefit of cooperative effort, he learned versatility. The great athlete was rare just as great genius was rare. In spite of abuses and extravagance the public interest in football was utilized by the state and the crowds who attended the popular football matches provided the dollars which financed rowing and the gymnasium. Intercollege rivalry was so keen that it was necessary to demand a certain standard of scholarship before a student was allowed to represent his college, and to circumvent the peripatetic athlete it was necessary to require a year's residence before a man could represent his university. The physical exercises offered a very wide range of selection. Usually three to four hundred students per annum required constant supervision. The man who grudged the time got concentrated exercise, but all were required to do a certain minimum. Athletic activities outside the college were not recognized and the student had to put in recorded attendances just as in any other course. Dr. Mackenzie ended by drawing attention to the fact that the universities had a great responsibility in connection with physical education, since they

received students from 18 to 23, in the last growing years of life. Logically, physical exercises should begin at school, but the years available at the universities were of special value. In Britain where a great swathe had been cut in the growth of young manhood, it was specially important to have the remainder in an efficient state of health. Sir Leslie Mackenzie, who joined in the discussion, said that if the best intellectual output were to be obtained the physical education of mankind should be cared for from conception onward. The revelations that followed the inquiry after the Boer War showed that out of every nine men from the industrial and general population only three were physically fit and healthy, two were slightly less efficient, the others were practically useless as soldiers. Physical training in the sense of the drill sergeant had a place, but physical education was the ideal. Under a system of physical education the intellectual output would at least be no less. Physical training was really a training of character.

Doctor Cruikshank, describing the physical education in the Scottish elementary schools, said the system was based on the Swedish system, but there were alterations tending to make the exercises more interesting. They tried to teach something more than drill. They inculcated personal hygiene and everything which went to improve the physical well-being of the individual. At Dunfermline there was a central institution for the training of teachers. They were taught anatomy and physiology, besides the more technical exercises.

Sir Montague Cotterill said that it came as rather a shock to him that physical training should take the form of anything approaching a lesson. Physical training was well taught at the public schools, but at the Scottish universities a disgracefully small number took any interest in the athletic side.

Honor to Sir Robert Jones.—Sir Robert Jones of Liverpool has received the Honorary Degree of Doctor of Science from Harvard University.

Meeting of the British Medical Temperance Association.—The primary object of this gathering was to hear an address by Sir Alfred Pearce Gould, who said in part it was a matter of common knowledge that the use of alcohol as a therapeutic agent had, during the past thirty years, rapidly and greatly lessened and it was the agreed opinion of pharmacologists that, in the very limited and lessening field of medical practice in which alcohol was still employed, it was of value only as a narcotic and not as a stimulant. He submitted that the medical profession had a very special responsibility in reference to the very widespread custom of the use of alcoholic drinks as beverages, and that the profession generally had not yet adequately realized and shouldered that responsibility. The alcohol question was really a problem in biology, and human biology was the special province of the medical profession. The speaker stated that the result of wide and long-continued observation, uncontradicted by any opposing observations, was to the effect that total abstinence favored and did not prejudice longevity. The medical profession need not be afraid of using all their influence upon the side of scientific truth in every detail of life, and not least, surely, in the case of a national habit that was the parent of so much failure, so much disappointment, so much sorrow and that marred the beauty of human life as did the drink habit.

1. Accessory Sinus Blindness. Differential Diagnosis and Operative Technic.—Leon E. White discusses objections and criticisms of his previous articles on this subject and summarizes as follows: (1) A careful differential diagnosis should be made in every case, but in the subacute or chronic forms it is of the utmost importance to rule out central lesions and toxic infections. (2) While a certain proportion of cases recover, either spontaneously or under treatment, permanent blindness may result in others unless they receive prompt surgical interference. The size and position of the middle turbinates determine largely the question of recovery with or without operation, and when found to be blocking the ventilation to the posterior sinuses they should be removed. (3) The opening of the accessory sinuses for the loss of vision, after the exclusion of other causes, has been advocated by many investigators, even with negative nasal findings. The fact that nothing is found either on inspecting the nose or by roentgenograms does not prove that there is no infection in the nose. It simply means that it cannot be detected. If the loss of vision is due to the accessory sinuses, there is pathology, but it may be located so far within the nose as to escape detection. As the inflammation incident to this infection is frequently of the exudative nonsuppurative type, the roentgenograms are practically negative. A more careful timing of the plates has shown a slight cloudiness in some, so it is hoped that the bugbear of negative nasal findings will soon be eliminated. (4) The complete ethmoid exenteration is not only unnecessary, but actually contraindicated, unless there is a sufficient pathology in the ethmoid labyrinth to warrant it, irrespective of the loss of vision. The semiradical sphenoid procedure, consisting of removal of the middle turbinate and opening of the sphenoid and ethmoid, is one practically devoid of danger, and can be performed under local anesthesia. It in no way impairs the function of the nose or needlessly imperils the life of the patient. It sufficiently drains and ventilates the regions adjacent to the optic nerve. Should, however, the visual disturbance be due to toxemia from some other sinus, or from teeth or tonsils, these foci of infection should receive attention. (5) While it is well to emphasize the dangers of this or any other operation in the hand of the unskilled, the fact is this sphenoid operation is frequently performed for much less serious complaints than loss of vision.

2. A Rare Fracture of the Lower End of the Humerus.—Luther G. Paul finds no mention of the fracture he describes after a moderately thorough search of the literature. A girl fourteen years of age was referred to him after having fallen down several steps. The left elbow was swollen and tender over the external part, and motion was much restricted on account of pain. Ether was administered, and after manipulating the part the writer was unable to make a diagnosis of the condition. The bony landmarks were in normal relation, and there was no abnormal mobility or crepitus noticed. On the following day an *x*-ray was taken. This showed a vertical fracture of the lower end of the humerus, in which the anterior part of the

articulating surface had been separated from the rest of the bone, and this fragment had been forced out of the joint, and was lying on the anterior surface of the lower end of the humerus, fully an inch above its normal position. After an unsuccessful attempt to reduce the fracture under ether, an incision into the joint was made on the outer side of the elbow, and the fragment found as the *x*-ray showed it. The only point of attachment of the fragment was by its inner end to a small area of the capsular ligament. It consisted of the capitellum and trochlear surfaces in one piece. Attempts to replace the fragment were unsuccessful until the following method was tried: The forefinger was placed in the wound over the fragment, and between the fragment and the tendons of the biceps and brachialis anticus muscles, the elbow being flexed to somewhat beyond a right angle. The assistant then extended the forearm, and at the same time exerted a pull, thus increasing the space between the humerus and the upper ends of the radius and ulna. The pressure exerted by the tightened muscles on the finger in the wound, together with pressure from the outside, caused the fragment to slip into place. The arm was put up in acute flexion. Three months later the movements of the joint were normal.

2. Diagnosis of Summer Diarrhea.—J. Claxton Gittings classifies the summer diarrheas of early life into two main types, one primarily due to infection of the intestinal wall and the other due to a disorder involving the intestinal contents. He acknowledges that it is often difficult or impossible to draw hard and fast lines of demarkation between these two types. The distinguishing feature of type one is that bacteria, usually introduced in food, drink, or by contact with infected articles, invade the wall of the gut and set up definite anatomical changes. Type two may be viewed as a functional disturbance rather than a somatic disease, since the basic disorder involves the intestinal contents rather than the intestinal walls. Infectious diarrhea has two chief synonyms, ileocolitis and dysentery. Both forms of diarrhea may be preceded by symptoms of indigestion, but as a rule the onset in both types is sudden, at least during hot weather. Toxemia will be present in both types, depending upon their severity. As a rule, however, the patient with functional diarrhea will show a higher initial temperature and more severe toxic symptoms than are seen in ileocolitis. The severe toxic cases of functional diarrhea show a suggestive facies, apathetic or stuporous, with dull, sunken eyes. Vomiting is not as common in the infectious as in the functional type. Anorexia is common in both types, but usually is more pronounced and protracted in the infectious type. Prostration depends upon the severity of the toxemia; it is likely to be more severe at first in the cases of functional diarrhea; later it is equally well marked in the infectious type. A distinguishing feature between the two types of diarrhea is that in general the functional type tends to an acute course with recovery or death, while infection of the intestinal wall speaks for chronicity. The characteristics of the diarrhea itself furnish the chief diagnostic points of difference. In functional diarrhea flatulence and foul odor to the stools are early symptoms, but the number of stools soon tends to diminish and blood is seldom seen. In ileocolitis the stools consist in large part of mucus, and the odor may not be especially offensive. Frequency is marked and persistent, blood is a characteristic finding, while abdominal pain and rectal tenesmus are present in the majority of cases. In the functional type the temperature tends to fall and assume a moderate irregular range. In ileocolitis, on the other hand, fever is constant throughout the active stage, tending to range between 100° and 102° or more for at least ten days, and, in protracted cases, simulates the temperature of typhoid fever. Membranous colitis resembles the severe forms of functional diarrhea and is characterized by the pseudomembranous patches sometimes seen on the prolapsed gut or shreds of it seen in the stools. Cholera infantum is a form of functional diarrhea usually given a separate place because of its characteristic symptoms. In making the diagnosis of summer diarrhea several other conditions must be ruled out as failure to recognize them may have most serious consequences. The appearance of blood in the stools in early life and especially in infancy should always suggest the possibility of intussusception. The presence of vomiting should suggest the possibility of meningitis, which often begins with a moderate diarrhea. Pneumonia, pyelitis, and even otitis media also may be ushered in with gastrointestinal symptoms. Typhoid fever may simulate ileocolitis, but in all these conditions the diarrhea is rarely severe enough to cause confusion. In the infectious types of diarrhea, specific treatment may be tried; diet certainly plays a much less important rôle than in the second type, in which it is of extreme importance. The occurrence of dehydration, even in mild degree, at once gives imperative indication for treatment. In the presence of a severe diarrhea, even before dehydration can be recognized clinically, appropriate measures for prevention should be inaugurated. An analysis of 100 cases of summer diarrhea at the Children's Hospital showed that thirteen were of the infectious type and eighty-seven of the functional type. The onset was recorded as sudden in every case in which the history was complete. Vomiting occurred as an initial symptom in 69 per cent. of the infectious cases and 71 per cent. of the functional cases. Blood was present in the stools in all the infectious cases. The mortality was 61 per cent. in the cases of colitis and 24 per cent. in the functional types. In only one-fifth the total number were the patients brought to the hospital on or before the third day of the disease. This may explain in part the excessive mortality in hospital cases.

5. Water Treatment in Diarrhea.—John D. Donnelly has employed sterile solutions of normal saline, five per cent. glucose, three per cent. sodium bicarbonate, and a glucose acacia solution, made up of glucose five grams, acacia ten grams, and normal saline sufficient to make 100 c.c. in the treatment of cases of extreme dehydration. The injections were made into the longitudinal sinus under the strictest surgical aseptic technic. By this method he has not experienced any complications or serious after effects; on the contrary, many of his results have been most striking in their beneficial effects. The only contraindications to this method are the various forms of infectious dermatitis, particularly if the scalp is involved. After having assured himself by animal experimentation that intraperitoneal injections were devoid of serious risk, he began using this method. After excluding abdominal distention and the possible presence of an overdistended bladder, with the child in the recumbent position, the injection is made through the median line just below the umbilicus. Usually 200 c.c. may be given to young infants in this way. The fluid should not be introduced too rapidly or in too large quantities so as to avoid possible embarrassment to the diaphragm and heart. A hypertonic injection of glucose (ten to sixteen per cent.) given intravenously after the intra-

peritoneal injection causes quicker absorption of the saline solution from the peritoneal cavity and urine excretion increases earlier than otherwise. Postmortem examinations on infants who had received intraperitoneal injections from a few hours before death to weeks previously failed to show any evidence of injury or infection of the peritoneum or abdominal viscera. The advantages of the intraperitoneal method of administering fluid to the dehydrated infant are: (1) Administration of large amounts of fluid at one time. (2) The fluid is quickly absorbed. (3) The method is a simple procedure, it is practical, and permits of repeated injections at frequent intervals with minimum risk to life. By this means one can help tide over the necessary period for readjusting the infant's feeding and gastrointestinal tract.

15. Prevention of Infectious and Contagious Diseases in a Children's Orthopedic Ward.—Walter G. Elmer reports that all the children brought for admission to the orthopedic ward of a general hospital in Philadelphia are examined for any evidence of throat infection, rash on any part of the body, and, in the case of girls, a vaginal discharge. The parents are questioned with reference to any recent contagious disease in the home or school or among the child's playmates. Cultures are made from the nose and throat, and specimens taken from all girl children to be examined for vaginitis. If these latter specimens are pronounced negative by the laboratory, the child is admitted to a probation room for five days. If the child has never been vaccinated, that is done during the first three days. Every child is immunized with diphtheria antitoxin during the same period. By the fourth day all the reports from the laboratory are returned. On the fifth day, after a careful inspection of the child's body, the child is transferred to the ward. Vaginal specimens are sent to the laboratory each week during the child's stay in the hospital. Every bed pan is surgically clean every time it is used. This plan has been entirely successful. It was put into effect in March, 1919, and up to the end of June, 1921, the ward has not once been quarantined.

3. The Acapnia Theory, Now.—Yandell Henderson, Howard W. Haggard, and Raymond C. Coburn present the following argument: Everyone admits that after a prolonged anesthesia and operation the blood alkali is diminished. This low alkali is the result either of the acidotic or of the acapnial process. If the former were involved the patient would have died instead of recovering. For in animals in which the alkali reserve has been diminished by intravenous injection of acid, the administration of carbon dioxide does not recall a normal amount of alkali to the blood. It cannot for the alkali no longer exists in the body. Such an animal when treated with carbon dioxide is overwhelmed by the acidosis, and usually dies. In acapnia the respiration is primarily excited; carbon dioxide is blown off, and the alkali falls secondarily as a compensation. If the blood alkali has been greatly reduced a condition of profound depression may continue for hours before the organism succeeds in reaccumulating the needed carbon dioxide and recalling alkali to the blood. Obviously the natural method of treatment is to assist nature to recover the normal equilibrium by restoring the carbon dioxide. This may be accomplished effectively by an inhalation device which the writers hope will soon be available for general trial and use. By means of it any amount of carbon dioxide may be administered to the patient mixed with the inspired air, but with no appreciable degree of rebreathing. That this treatment works effectively and beneficially affords crucial evidence in support of the acapnia theory.

9. Pyrethrum Dermatitis.—Carey P. McCord, C. H. Kilker, and Dorothy K. Minster report the finding of an occupational dermatitis among the workers engaged in the manufacture of pyrethrum insect powder. Chemical analyses have established various constituents having irritant properties. The lesions noted are, essentially, various forms of dermatitis venenata. They are of mild severity and quickly disappear under ordinary treatment. Reexposure frequently leads to recurrence of the disease. This dermatitis may be prevented by the introduction of trade processes that eliminate the necessity of exposure of workers to pyrethrum dust and powder. In the absence of such machinery scrupulous personal cleanliness of the worker is requisite. On starting work in the morning and at noon, cold cream, petrolatum and the like should be applied to the exposed parts of the body. At night the arms, hands, and face should be bathed in water containing sodium bicarbonate, a teaspoonful to a gallon of water, since the irritating substances are probably acid.

11. The Incidence of Cancer in the Second Breast, after Radical Removal of One Breast for Cancer.—Alson R. Kilgore has studied the records of 1,100 unselected breast carcinomas operated upon in the surgical service of the University of California Hospital. The results in 659 cases were known for three years or more after operation. Only 257 of the 659 patients traced were living at the end of three years. A study of the facts brought out in this series of cases indicate that the patient who has had one breast amputated for cancer is, if she survives five years, from three to four times more likely to develop cancer in the second breast than a normal woman of the same age in either of her two breasts. The majority of cancers in second breasts, arising three or more years after the first operation, behave, clinically at least, like primary new growths—not like metastases from the cancer in the first breast. These facts demand recognition, either in the form of prophylactic removal of the second breast or redoubled care in observation of the second breast after operation on the first. The records in this series suggest that if the 257 women living three years after the first operation had submitted to prophylactic resection of the second breast, twelve cancers and ten deaths from cancer in the second breast would have been prevented. One patient in five had no involvement of the axilla at the time of the first operation, and if these patients had their second breasts excised, three out of four cases of late cancer in the second breast would be prevented. The writer states that the object of his paper is distinctly not to lay down as a surgical principle the prophylactic removal of the second breast, but simply to bring out the fact that the increased incidence of cancer in the second breast is sufficiently interesting to demand attention.

13. The Removal of Bile and Blood from the Urine in Performing the Phenolsulphonaphthalein Test of Renal Function.—C. Sidney Burwell and Chester M. Jones call attention to the fact that bile and blood are two common sources of color in the urine that render the phenolsulphonaphthalein test of renal function inaccurate. The method which they describe removes both bile and blood. It consists of the precipitation of bile and blood by zinc acetate and their removal by filtration. This procedure permits practically 100 per cent. of the phenolsulphonaphthalein to remain in the filtrate. This modification of the usual phthalein test is extremely simple, and should prove particularly applicable to cases of choluria and hematuria in which a study of the renal function is indicated.

1. Objective Study of Neuroses.—F. L. Golla points to the fact that through our concentration on the cerebral aspect of mental activity we have been slow to perceive that the body partakes in the movements that express this activity, and that by ignoring these bodily signs the possibility of establishing an objective standard in our interpretation of neurotic disturbance is, to a great extent, lost. The point of view that he deals with in these lectures has for its object an attempt to define in objective terms the chief data that may lead us ultimately to formulate the nature of the physical disturbance of mechanism that constitutes the primary factor in the neuroses. That such a physical disturbance is the cause of the neuropathic condition and precedes its manifestation he holds very strongly. One fact emerges from all the investigations that have been conducted in recent years by the methods of analytic psychology, and that is that in the vast majority of cases the experiences of the neurotic differ in no way from those that fall to the lot of ordinary healthy men. The data furnished by the war are cited to the contrary, but they really furnish irrefutable evidence that an organic disturbance or failure of organic equilibrium preceded the neurotic symptoms and could not have been caused, however much it may have been aggravated, by the individual experiences, because millions of men were exposed to the same conditions, yet only a small number were brought to our hospitals suffering from a neurosis. Thus Golla thinks we are justified in assuming that an organic disability exists as an antecedent to every neurosis, and in employing methods for objective evaluation of organic efficiency in looking for it. Such study must be conducted along many lines of observation, but broadly speaking there are two methods at our disposal—the study of conduct and the study of specific bodily reactions or movements. The movements which he has studied and discusses are of two types—those which are the exterior manifestations of the specialized response of certain nervous mechanisms, and those which connote the generalized reaction of the body as a whole to stimuli which disturb or threaten the unity of vital action. Thought as a mode of movement, the connection of muscular tension with intellectual or physical effort, and measurements of alterations of muscle tonus, effort in connection with head movements, respiratory movements and circulatory reaction are discussed for the purpose of giving some brief account of the movements that are the objective expression of effort.

3. A Note on the Mortality of Premature Infants.—Thomas Watts Eden presents data based on the analysis of statistics from six different institutions from which three points of interest are gleaned: (1) Babies born at 36 weeks or 37 weeks in one hospital are on an average nearly a pound heavier than those born during the corresponding week in a second hospital. (2) Babies born prematurely vary in length and weight to as great, or perhaps to a greater, extent than do babies born at term. (3) The relationship between length and weight is subject to very wide variation; premature babies may be long and light, or slight and heavy. It has been suggested by Frank that the ratio of length in centimeters to weight in grammes is different in mature and premature babies. The writer has tested Frank's formula over a large number of cases and does not find it reliable. These figures show that from 30 to 45 per cent. of premature babies die in lying-in hospitals, and if a selection is made of those babies which have no obvious disability in addition to their prematurity, less than two-thirds survive their third week. The percentage of mortality of these selected premature babies during this first period may be anything from 35 to 50 times as great as that of mature babies born under the same or similar conditions. The figures as would be expected show how rapidly the mortality rate falls from the thirty-fifth to the thirty-eighth week. A comparison of these statistics with those of Budin show that his results 20 years ago were as good as our own to-day. The need of following up premature infants after they leave the hospital is emphasized. Budin presented figures showing that his premature babies had as good a chance of survival as normal babies, so long as they were breast fed, but if bottle-fed they did very badly, the mortality in the latter case being nearly three times as high as in the former. The unsatisfactory results at present obtained in the management of premature babies should induce all who are concerned with the lying-in hospitals to consider the whole matter afresh.

1. Observations on Malignant Granuloma of the Nose.—Robert Woods reports two cases of a disease which he believes has hitherto been undescribed. The first case was that of a man 68 years of age. On examination, the bridge of the nose was sunken just below the nasal bones. Both sides of the nose were filled with fetid crusts, the cartilaginous septum was gone, some of the soft tissues were deficient, and the walls of the nose in a condition of ulceration. The patient was well nourished, no glands were enlarged, and the condition was strictly a local one. The Wassermann reaction was negative and anti-syphilitic treatment had no obvious effect. It seemed as though a wave of granulation tissue advanced irregularly into health parts, breaking down behind as it advanced in front, so that there was never any great depth of pathological growth present. The patient lived for four and a half years after coming under observation. The discomfort of the condition as it progressed was never sufficient to require the use of anodynes. Repeated efforts were made to discover some organism to which blame might be attached, but always without success. *X*-ray treatment was ineffective. The second case was quite similar except that a clinical cure was effected by application of radium tubes. The case was seen by a number of the writer's laryngological colleagues, who confessed that it was unique in their experience. The presumption is raised that the granulation tissue, instead of being an evidence of attempted healing, is itself the primary cause of destruction. Until we understand what is meant by a cell taking on malignant action we cannot doubt that what happens to one kind of cell may happen to another, and if we can have a malignant epithelioma, why not malignant granuloma?

3. Treatment of Asthma by Autogenous Streptococcal Vaccines.—Leonard Rogers during the past seven years has used this method extensively in Lower Bengal, which is notoriously unfavorable to asthmatic patients. Forty cases of well-marked asthma are included in the series. The method used consisted in simply making cultures from the sputum, subculturing a number of colonies of streptococci, including any short chain pneumococci, and making up a vaccine of the strength of 100 millions in 1 c.c. The initial dose was ½ to ¼ c.c., and as soon as no reaction ensued larger dosage was gradually increased. The treatment usually had to be continued for two or three months and sometimes longer. In 15 per cent. of the cases the treatment failed to give material relief of a lasting nature. In 32.5 per cent. great relief was afforded, but it was either not permanent or it was incomplete. In 52.5 per cent. the patients remained well when last heard from, one-half to four years after the treatment. The results seem to be due to immunization against the streptococcal group of organisms which is a common

excitant of asthmatic attacks in persons liable to them.

6. A Plea for the More Frequent Use of Cesarean Section. With Description of a New Operation.—Arnold Jones describes an operation which he has devised with a view of leaving a scar which he believes will stand the strain of future pregnancy. It is based on the fact that there are three layers of uterine muscle, the outer and middle layers of which are easily differentiated during pregnancy. The superficial layer is incised transversely just below the center of the body in front and 2 inches above Bandl's ring. The superficial layer is peeled free from the middle layer. The middle and inner layers are incised longitudinally, the line of incision chosen being that which is most free from blood vessels. This is usually but not always the midline. After delivery of the child and placenta the incisions are closed by continuous No. 4 catgut sutures. The two scars not only run at right angles but are not opposite one another.

6. Letters to a Young Physician. Alfred Kahn.

2. Twentieth Century Baldness.—Charles F. Pabst applies this term to premature baldness. Prophylaxis is of vast importance, and consists of daily brushing of the hair and well-regulated habits of hygiene. If the hair is dry, he recommends a few drops of liquid vaseline applied every third day. Wetting, other than with a properly ordered shampoo with soap and water every three weeks, singeing, cutting, or shaving, the application of electricity, and undue exposure to sunlight are not beneficial and may be harmful. Exposure to natural sunlight should be undertaken only when the sun's rays are properly regulated, and under the direction of a competent physician. General treatment involves tonics and exercise, drinking, eating, and mental effort in moderation. The point is made that baldness is not as common in vegetarians as in meat eaters. Local treatment embraces soap and water shampoo, using mild, non-medicated soap every three weeks, and gentle digital massage every day. The local applications vary according to the condition of the patient's scalp. The writer usually begins with a 10 per cent. precipitated sulphur ointment, followed, when the hair ceases to fall, by a mild, stimulating lotion, gradually increasing the strength until the desired action is obtained.

4. Prognosis in Nephritis.—H. G. Webster discusses the varied and picturesque classification of the nephritides, and says that after all the question is not whether the patient is suffering from acute nephritis, or from subacute nephritis, or from chronic nephritis with edema but if he will recover from his present condition and how long he will live. In analyzing the case of any patient in whom the presence of casts or albumen, or blood elements in the urine has attracted attention to an inflamed kidney we must consider not only the chemical and microscopical condition of the urine, but the blood chemistry and the subjective and objective symptoms of the patient, and more particularly the changes in the heart and blood vessels. It is in the proper estimation of these factors and their relation to one another that the present state and future probabilities of the individual depends. Because in many cases the blood pressure is high one must not fall into the fallacy of regarding high blood pressure as an essential symptom, because many fatal cases show low blood pressure. Because albumen and casts are usually present one must not feel too well assured of a harmless condition if albumen and casts are not present, for fatal cases with this finding are by no means rare. Because of extensive edema one should not despair of the patient's condition, because such cases sometimes clear up completely and make a clinical recovery. For purposes of clinical study it is well to group cases according to the length of time that symptoms have been present; according to the age of the patient; according to the presence of disease of other organs, and according to the intensity of the symptoms. Though this is a loose and elastic method, it serves as a point from which to start. There is one distinct picture which should be excluded from among the nephritides where it has long been placed, and that is the considerable group of people of advanced years who show a constantly high blood pressure, ranging about 200, with the passage of large amounts of watery urine of low specific gravity, containing an occasional trace of albumen; hard and tortuous arteries; more or less compensatory cardiac changes, and some evidence of nervous instability. In spite of their disability they live to a ripe old age. In diagnosis there is sometimes failure to appreciate the frequency with which anorexia, nausea, vomiting, and intestinal gas are associated with nephritis; these symptoms should be regarded as definite finger-posts pointing to the kidney as well as to the gastrointestinal system. Focal infection as a factor in causing kidney inflammation must not be overlooked.

Wiener klinische Wochenschrift.

Psoriasis.—Unna gives a terse summary of the history of our knowledge of this dermatosis and its autonomous position, with especial reference to the differentiation of psoriasis and seborrheic eczema. In certain cases this appears almost impossible clinically. The latter appears to represent a gradation between essential psoriasis and dry eczema. Between these two extremes the greatest variability of eruption occurs, which one may term atypical psoriasis or atypical seborrheic eczema, according to the case. An autonomous psoriasis is, therefore, more or less in doubt. From another angle there are analogies between psoriasis and tinea trichophytina, clinical and therapeutic, which suggest a possible mycelial origin of the former. We have long known that psoriasis papules may be produced artificially—for example, by scratching—which suggests inoculation with some microorganism. The behavior of erythema multiforme, however much it suggests a parasitic origin, has always lacked the serpiginous component seen in known parasitic affections. A placque grows peripherically as it clears in the center and several rings may coalesce to form characteristic patterns, but, as stated, there is none of the serpiginous extension seen in known parasitic affections. But in psoriasis we see serpiginous extension. There is, in fact, abundant evidence that psoriasis cannot owe its patterns to vascular or nervous influence. Quite suggestive of the parasitic origin is the apparent lurking of the causal agency in unhealed lesions from which new infection constantly occurs; and success in treatment is bound up in the thoroughness with which these foci are sought out and cured and in the care of the skin from a prophylactic standpoint. In the case of psoriasis universalis, conditions are unfavorable, especially as our best remedies, pyrogallol and chrysarobin, are not applicable on so great a scale. The hands may be treated with pyrogallol in the possible hope that autoinfection may be antagonized. The body at large may be treated with a mixture of chrysarobin, salicylic acid and ichthyol, but only for a short time or until a certain inflammatory reaction is produced. A zinc sulphide paste is then used to follow up, and the skin should clear up, with the exception of certain obstinate lesions, which should receive intensive treatment. When the subject seems clean, the skin should be anointed with a prophylactic ointment or oil containing salicylic acid, white precipitate, or other antiparasiticide.

Book Reviews.

MENTAL DEFICIENCY (AMENTIA). By A. F. TREDGOLD, M.D., F.R.S., Edin., Fellow of the Royal Society of Medicine; Consulting Physician to the National Association for the Feeble-Minded; Consulting Mental Specialist to the Willesden Education Authority; Vice-President Central Association for the Mentally Defective; Formerly Lecturer at the Medical Graduates' College, London; Medical Expert to the Royal Commission on the Feeble-Minded; Research Scholar in Insanity and Neuropathology of the London County Council and Assistant in the Claybury Pathological Laboratory; Resident Clinical Assistant in the Northumberland County Asylum, etc. Third Edition, Revised and Enlarged. Price, $6.00. New York: William Wood & Co., 1920.

THE second edition of this book was exhausted in 1915; but in this, as in many other instances, the war interrupted plans for further revision. Now, however, we have the third edition, thoroughly revised and brought up to date, with some parts entirely rewritten. The text is arranged in twenty-two chapters dealing, respectively, with the nature of mental deficiency; incidence; causation; pathology; classification; neurophysiology and psychology; the physical characteristics of amentia; feeble-mindedness in children (mentally defective children); feeble-mindedness in adults; imbecility; idiocy; clinical varieties of primary amentia; clinical varieties of secondary amentia; "idiot savants"; insane aments; vicious and criminal aments; moral imbecility; mental tests and casetaking; diagnosis and prognosis; treatment and training; the law of England concerning amentia; sociology. An appendix is devoted to nomenclature, embracing tables of synonyms, normal development data, and anomalies associated with amentia. A frontispiece and twenty-nine plates illuminate the text.

VENEREAL DISEASES, Their Clinical Aspect and Treatment. With an Atlas of 106 Color and 21 Half-tone Illustrations. By J. E. R. MCDONAGH, F.R.C.S., Surgeon, London Lock Hospital; Late Hunterian Professor, Royal College of Surgeons, Etc. Price, $20.00. London: William Heinemann; St. Louis: C. V. Mosby Company.

THIS is a noteworthy book in several respects—its size and handsome appearance, the great number and beauty of its illustrations, its exhaustive treatment of the chief venereal infections, and the fact that it has no preface. The author, as is known, disputes the generally accepted views regarding the pathogenic microorganism. He accepts the *Spirochæta pallida*, but holds that it is merely the adult male of a coccidial protozoon *Leucocytozoon syphilidis*. He also holds that the Wassermann reaction "is simply a physical reaction dependent upon the increased number and size of the protein colloidal particles in the serum, and that salvarsan destroys the parasite only indirectly by increasing the oxidizing action of the host's protective substance." Thus he opposes the three alleged discoveries of Schaudinn, Wassermann, and Ehrlich, which he calls the "German syphilitic trinity." The proof of these views is not attempted in the present volume, which is purely clinical, but is promised in a special pathological volume to be published shortly. The practical application thereof is, however, made in the text of the present volume—for example, in the description of the mode of formation of the primary sore (p. 13), the rationale of conceptional syphilis (p. 253), explanation of the escape of the nervous system in many cases of syphilis (p. 113), etc.

In spite of these somewhat heterodox views regarding the causal agent in syphilis, the author's method of treatment is eminently orthodox, even though not altogether conventional. He employs the arsphenamine group of remedies, but does not rely upon them exclusively, making use of mercury, sulphur preparations (intramine), and colloidal iodine. The latter, he claims, breaks up the colloidal protein particles in the blood serum into smaller ones, thereby increasing their receptivity for the arsphenamine.

The author also treats of gonorrhea and chancroid very thoroughly and satisfactorily so far as regards their symptoms and treatment, though, as in the case of syphilis, he does not take up the pathological or microparasitical aspects, which are reserved for a special volume.

INFECTIOUS DISEASES. A Practical Text-book. By CLAUDE BUCHANAN KER, M.D., Ed., F.R.C.P. Ed., Medical Superintendent, City Hospital, Edinburgh, and Lecturer on Infectious Diseases to the University of Edinburgh, Major, R.A.M.C., T.F. Second Edition. London: Henry Frowde, and Hodder and Stoughton; New York: The Oxford University Press, American Branch. 1920.

THE first edition of this work appeared in 1909, and the second edition was scheduled for 1914. The war interfered with the publication, at that time, of the revision, and in the meantime so much work has been done in the field of infectious diseases that the second edition, as it now appears, involves extensive alterations and additions, and the remitting of several portions. Like others of the Oxford Medical Publications, the book is excellent with respect to paper, typographical display, illustrations, and binding. The text comprises 609 pages, and includes 32 plates and 68 charts. The fifteen chapters include an introduction which deals with bacteriology, infection, the incubation period, and other subjects common to all infectious diseases; measles, rubella, scarlet fever, smallpox, vaccinia, chicken-pox, typhus fever, enteric fever, diphtheria, erysipelas, whooping-cough, mumps, cerebrospinal meningitis, and fever hospital problems.

BLOCK ANESTHESIA AND ALLIED SUBJECTS. With Special Chapters on the Maxillary Sinus, the Tonsils, and Neuralgias of the Nervus Trigeminus for Oral Surgeons, Dentists, Laryngologists, Rhinologists, Otologists, and Students. By ARTHUR E. SMITH, D.D.S., M.D., Oral Surgeon to Francis Willard Hospital and to House of Good Shepherd, Chicago. 595 Illustrations. Price, $15.00. St. Louis: C. V. Mosby Company.

THIS great book of 895 pages is devoted to the subject of local anesthesia in all its uses and relations. While simple local anesthesia, in its usual significance as distinguished from block anesthesia, receives full and satisfactory consideration, it is, as the title implies, to the latter as employed in dental, oral, and facial surgery that the larger part of the work is devoted. A brief introduction gives the history of surgical anesthesia in which the claims of all the aspirants are set forth, but the prize for prior demonstration and publication is conceded to Morton.

The description of the technique for blocking the various nerves preliminary to tooth extraction or filling, to resection of the jaw, tonsillectomy, and various operations on the face and neck is given in great detail and nothing is left to the intuition or the guessing of the young operator. This is a special feature of the work and one that will render it of extreme value to the dentist or surgeon, in rural disticts especially, who has to do his own anesthetic work or see that it is properly done by a perhaps insufficiently trained assistant.

Two chapters are devoted to accidents and post-anesthetic complications such as broken needles, hematoma, after pains, syncope, and shock. The book is well printed and the numerous illustrations are a delight to the eye as well as extremely serviceable in making clear every step in the innumerable blocking operations.

KLINIK UND THERAPIE DER MALARIA. Von Dr. EMMERICH WIENER (Budapest), der zeit k. u. k. Oberarzt, Abteilungschefarzt. Berlin und Wien: Urban & Schwarzenberg, 1918.

THIS pamphlet presents a fairly extensive study of the several clinical forms of malaria with a discussion of the differential diagnosis of the disease and its treatment. It is deficient on the pathological side not only in the description of the organ lesions which occur in the disease but also in the changes which have been noted in the blood. The discussion of these factors is so brief as to have but little value. The symptomatology, on the other hand, is quite fully presented, and therapy also is fairly well written up. It is doubtful if this booklet would find much favor in this country, since there are a number of articles on the disease, written in English by American physicians, which are quite as complete and much more readily available.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Eighty-ninth Annual Meeting, Held at Newcastle-on-Tyne, July 15-23, 1921.

(Special Report from Our London Correspondent.)

Hospital Management.—The representative meeting was under the presidency of Dr. GARSTAN. A series of resolutions were discussed with regard to the methods which should be adopted in the conduct of hospitals in the future. Mr. Bishop Harman moved these resolutions on behalf of the council. The first proposal declared that the voluntary method of administration of the voluntary hospitals was to the advantage of the public, of medical science, and of the medical profession and that it should be maintained. Mr. Harman pointed out that the essence of the voluntary system was the independence of administration. Dr. E. Rees remarked that the council were asking them to pass a resolution which was not expressing the exact truth. The voluntary method could no longer preserve the hospitals in the necessary state of efficiency. A great bogy had been brought before medical practitioners. It was very popular with those who objected to an endeavor to put things on a communal basis, because it condemned anything in the nature of what was called socialism. As an educated body they ought to be above that sort of thing. Dr. Fleming said that the experience of public authorities was that they had not got the hospital spirit and the desirable appreciation of scientific work and research. The motion was carried.

The subject of the free treatment of poor patients was then dealt with, and it was resolved that inability to pay for adequate treatment should be the consideration for the admission of all patients for hospital treatment. Dr. Rees said that all people who were admitted to hospitals free should be admitted as citizens. The old idea that they were to be regarded as paupers was horrible. Every citizen should have the right of admission to a national hospital for treatment. The idea that they should be objects of charity was abominable. Another resolution was carried stating that it was undesirable that the voluntary hospitals should be subsidized by the local rating authorities, except in so far as payment was made for the examination and care of patients for whom those authorities were responsible. A resolution was also brought forward advocating that the government should subsidize voluntary hospitals when they were in financial difficulties proportional to the income received by the hospital from voluntary and other contributions. It was further affirmed that greatly extended support for voluntary hospitals should be sought from employers and insurance companies, seeing that they benefited largely, both directly and indirectly, by the services of the voluntary hospitals. Another resolution passed declared that every patient of a voluntary hospital, who was able, should make a contribution, during treatment, towards maintenance, unless the contributory method of subscription was adopted as essential in industrial areas, and that in view of the increased cost of maintenance the contributory rates paid by workmen should be materially increased. Yet another motion adopted was that where voluntary hospitals provided accommodation for paying patients no fixed rate of payment for professional services rendered to such patients should be established. The fees so payable should remain, as at present, a matter of arrangement between the patient, the family physician, and the consultant.

The meeting on the recommendation of the council, adopted a resolution maintaining that the essence of the voluntary system was the independent and voluntary management, and that this was in no way related to the conditions of service of the medical staff.

Poverty and Tuberculosis.—The question of poverty as a means of raising the rate of tuberculosis mortality was one of the most interesting matters discussed.

Dr. B. G. BASKETT, in introducing the question drew attention to the slackening of the fall in tuberculosis mortality in Great Britain from 1896 onwards, culminating in an actual rise in the death rate after the insurance act, and suggested that the council be instructed to institute an inquiry into the effect of the act upon the nutrition of the poor. The national mortality from tuberculosis, he said, depended upon the rate of real wages. He had been studying the subject for twelve years, and had never yet found a case where a rise in the death rate had not been preceded some three years previously by a fall in real wages nor had he seen the converse. Tuberculosis mortality was a very sensitive index to economic conditions and unless wages were raised, he declared that the death rate would not fall. For a long period, from the forties down to the end of Mr. Gladstone's life, there had been a continued fall in the death rate of about 200 per million, and Mr. Gladstone saw it fall during his lifetime by 2,000 per million. Then came a rise, and now the rate was going down again. If the rate had continued to fall at the same rate as during Mr. Gladstone's life, there would now only have been 400 deaths per million instead of 1,000 as was actually the case. That meant that 600 lives per million were at present being wasted. If it depended upon real wages, then he contended that the problem for the statesman was to raise real wages, in other words to act so that prosperity might be diffused. But he asked if this was achieved by the insurance act.

Narcotic Drugs.—Commenting upon the draft regulations of the Dangerous Drugs Act, 1920, Dr. TURNER said that the association took very prompt action immediately these regulations were put forward. As a result of their action a committee had been set up after many points definitely decided by the Home office, and practically the whole of the objections raised by the medical profession had been sustained. The original draft required practitioners to keep in special books records of all purchases and supplies of the drugs, morphine, cocaine, ergonine, heroin, and medicinal opium, and these records were to be open at any time to inspection, presumably by the police. Apparently, a separate set of books would be required at each branch surgery and call house. A prescription in writing was to be given whenever the drugs were ordered. The name and amount of the drugs was to appear on any bottle or package containing the drugs. The draft regulations, seemingly, placed quite unnecessary difficulties in the way of the drugs being got by patients or used by doctors, and showed an astonishing ignorance of the conditions of practice.

The General Meeting was held on the evening of July 19.

Sir CLIFFORD ALLBUTT, the retiring president, in relinquishing his office said that in the performance of his duties during the past five or six years the reward had been his, first, because of the great advantages he had derived from the friendship of those connected with the association, and secondly, in having been allowed to see from the inside the working of the association. He then introduced the new president, Professor David Drummond.

The President's Address dealt with the future of the medical profession, the right of medical practitioners to claim post-mortem examinations as the only true means of insuring accuracy in diagnosis, an admittedly revolutionary suggestion, which, to become effective would require the endorsement of a public opinion at present dominated by prejudice, was one of the outstanding proposals for the advance of surgery put forward by Dr. Drummond. He pointed out that diagnosis, at present, was in very many cases only a matter of opinion, which must remain in doubt unless cleared up by an autopsy. In making that statement, however, he trusted it would not be thought he was casting any blame upon the doctors, for the marvel was that the opinion expressed was so often correct. A prominent member of the profession had recently said to him that the one thing above all others calculated to elevate and generally improve the standing of the general practitioner was opportunity for post-mortem verification or the contrary of his expressed opinion, and the speaker insisted that we should be entitled to claim, with the knowledge that we should not be denied, a post-mortem examination. Revolutionary it certainly would be, Dr. Drummond went on to say, but what an enormous gain to have our doubts set at rest, and it was not too much to hope that before very long both the public and the profession would be educated up to

feel that truth before all things must prevail. It was, perhaps, unnecessary to insist upon the enormous advantage it would be were post-mortem examinations universal. He said there should be in every large teaching hospital connected with a medical school a statistical department, with a highly trained official at its head, whose duty it would be to collect and systematize all returns. At present the returns were grossly inaccurate and therefore many of the deductions were necessarily fallacious, while, for want of a proper system, the waste of what might be called raw material was simply appalling. Observations of interest were being made daily in the wards, post-mortem rooms, and the adjacent pathological and chemical laboratories of which use was never made. The work in every hospital ward, post-mortem room, and scientific laboratory engaged in the investigation of disease for the purpose of teaching, should be regarded in the light of research. The establishment of whole-time professorships in medicine, surgery, and midwifery would help very greatly to promote this most important side of the teacher's functions.

Dr. Drummond said the profession was not satisfied with the position it occupied in the scheme of national polity. It was evident, he said, that they were becoming an indispensable factor in the government of the country. The state would soon realize the great weight of responsibility that belonged to every medical man, and he was anxious that it should not be left to the state to bring it home to the profession. If a member of our profession was to do his duty by the community and fulfill his professional obligations in a satisfactory manner, he must continue his education during the whole of his professional career. The history of the general practitioner ought to be a record of unvarying progress.

Sir DAWSON WILLIAMS, editor of the *British Medical Journal*, was presented at this meeting with the gold medal of merit of the British Medical Association, in recognition of his distinguished services to the profession. The medal of merit was instituted by the association in 1887, and is awarded by the council only for very distinguished services to the association.

The Ministry of Public Health.—In the Section on Preventive Medicine over which Sir Thomas Oliver presided, Dr. Modlin said that the medical profession had worked for a long time for a Ministry of Health, and had asked that the minister should be a medical man. He was not going to answer the question whether it had been a success from the point of view of the health of the people, or whether the benefits of legislation were commensurate with the enormous cost to the nation. He did not think they could wonder that local authorities harassed by fear of rate-payers and increasing rates, and pressed by government orders, which were continually changing, hesitated to rush in without knowing what they were letting themselves in for. But the health of the people must be the first consideration, and he hoped the section would consider whether the matter was best left to local authorities and private effort.

The Effect of Health Legislation on the Health of the People.—Captain WALTER E. ELLIOTT introduced this discussion. He said that the more one looked into the problem the more one was impressed with the enormous value of prevention as against cure, and so far as could be made out prevention could only me really brought about by the compulsion of some statutory enactment or other. Captain Elliott went into the history of health legislation and declared that the treatment had not advanced in the same degree as had legislation. The death rate and the infantile mortality rate had gone down since 1850 and he did not think that medical skill alone could have brought this about. In no small way it was due to the power of the policeman. The supply of water, first dirty water and then pure water, was one of the examples of legislation's effect on the health of the people. The factory legislation had had an enormous effect, too, and it was largely agitated for and driven home by laymen. Lord Shaftesbury was largely responsible, but not many public monuments were erected to him; and there was not a single portrait of him in the House of Commons, though he had more effect on the health of the nation than fifty of the commonplace busybodies who were glorified there. The compelling hand of the state was in many ways a great evil, but to deal with the manufacturers of the forties (1840 to 1850) no less an authority than the state was capable of tackling the problem. The conditions under which the manufacturing population were allowed to live were still reflected in the North. The South was still better than the North in the matter of children. There was at present a great wave of feeling against state interference of any kind; but it would be fatal and tragic if it allowed any to despise or ignore the great results which had come about from public health legislation in the past. The lay population had forgotten the benefits, and they resented the shepherding to which they were going to be subjected. It was interesting to note that diseases which had been regulated had lessened, while other diseases had not diminished proportionately. Measles, for instance, was responsible for 9,000 deaths in 1871, and the mortality was still 9,000 a year. Dealing with the statistics for tuberculosis the speaker said he had tried to find reason for the rapid post-war fall. It was said by some that the influenza epidemic which swept the country like a broom, cleaned out all the weak chests; but the fact remained that nonpulmonary tuberculosis had declined also. There was the great wave of unemployment, 22 per cent. in May, and the vital statistics of this country were not apparently suffering to any great extent at the present time, but there were four million producers not producing, and the debility and starvation diseases were not showing themselves to any great extent. In conclusion he asserted that legislation had done enough to warrant them continuing on the same path.

The Importance of Industrial Medicine to the Community.—Professor E. I. COLLIS introduced, in the Section of Preventive Medicine with Industrial Diseases, a discussion. He said that previously the public came in contact with the profession only in case of illness. Questions affecting the maintenance of health were impersonal and left to the public service concerned with the water supply, drainage, etc. More recently, however, the personal note had been sounded in relation to maternity and infant welfare, school medical service, and venereal clinics. Adult life was just touched, but generally speaking, means had yet to be found for bringing preventive medicine into direct contact with the adult. For this purpose industry, which gathered the adults together, provided the means. The points were, whether the community would benefit, if industry shouldered the responsibility and whether industry itself would benefit. The benefits to both were closely interlocked. Regarding the health of the industrial population, army recruiting data showed that only 36 per cent. of the male adults were classed Grade I. The miner and the agriculturist provided higher proportions than any other industrial groups. The peculiarities of industrial disease were important in drawing attention to the influence of occupation upon health. Industrial medicine was recognized to be directly aimed at preventing disease and maintaining health. The state was undertaking to bring up to adolescence healthy individuals. Employers must in turn maintain that health. The state strove to instil the principle of health up to adolescent life. The youth passed into some occupation, and found no attention paid to health and its maintenance. There were immense possibilities in industry. A standard set by the capitalist would spread from the factory to the home. The drift of workers from one place of employment to another was now recognized to be a heavy economic burden upon employers and employed. Various calculations in America and elsewhere placed this labor turnover at a figure which in some cases attained to 400 per cent. The high labor turnover was unnecessary, as had been shown both in the United States and here; it fell to 30 per cent. where medical supervision of entrants and hygienic conditions of employment existed. This would mean a saving of seventy million pounds a year. Careful inquiry had established that the underlying cause at the back of lost time was either certificated sickness or that condition of lowered health which preceded sickness. Various estimates of lost time had been made. In some cases it amounted to 20 per cent. of total possible hours; but when health conditions were favorable it might

fall below 4 per cent. An average of 10 per cent. probably was not excessive for half the employed population, while 4 per cent. might be taken for the other half.

Industrial Hygiene: Its Rise, Progress, and Opportunities.—Sir THOMAS OLIVER gave an address on this subject. He said that industrial hygiene might have merged out of Parliamentary interference with the claims of employers to utilize labor almost to its breaking point. Occupation was never meant to cripple workmen, cause ill health, or induce early death. It was thus that medicine was drawn into the social movement, in which it played an honored part today. Within the past few years the scope of industrial hygiene had widened. Today industrial hygiene was no longer the affair of one nation, but of all the advanced nations. The creation of the International Labor Bureau had raised industrial medicine to a higher platform. Medical examination of workers before commencing their industrial career would no doubt create hardships, but the ultimate gain would transcend all these. After discussing lead poisoning, phosphorous poisoning and fatigue, the speaker said in conclusion that since industrial medicine had come to stay, facilities would in the future have to be provided to medical students and young graduates to become familiar in a practical manner with its objects. The prosperity of the nation was intimately bound up with the health of the people who composed it. Preventive medicine had, practically speaking, swept the British Isles clear of typhoid fever and considerably reduced the mortality of diphtheria. What it had accomplished on the side of public health it could also accomplish in regard to occupational disease. There was a psychology of industry just as there was a physiology. Psychology was no longer simply "the science of mind or soul" but "the science of the facts of human nature and behavior," and there was no department of human activity which offered greater scope for its study and application than industry. Employers no longer regarded "industrial hygiene" as something to be turned down on the ground of its interference with labor and the conditions under which it was carried on. They recognized that it introduced into industry just that something with a touch of humanity in it which softened the asperities of labor, made occupation more healthful, and tended to bring employers and employed into closer touch with each other. Had it not been for "welfare work" carried on during the years 1914 to 1918 the enormous production of munitions could hardly have taken place and without it the war would have been lost.

AMERICAN THERAPEUTIC SOCIETY.

Twenty-second Annual Meeting Held in Washington, D. C., June 3 and 4, 1921.

First Day—Friday, June 3.

(*Continued from page 303.*)

The Prevention of Venereal Disease.—Dr. THOMAS E. SATTERTHWAITE of New York presented this paper. (See page 311.)

Dr. JAMES M. ANDERS of Philadelphia said that prophylaxis in venereal disease was essentially a medical question and that from the medical profession must emanate efforts to solve the vexed problem. This being unquestionably true, they should realize their responsibilities, more particularly since, as Dr. Satterthwaite had just emphasized, these diseases had been more prevalent since the World War than prior to 1914. It had been thought that the prevention of venereal disease could be dealt with by Boards of Health, *e. g.*, by making notification compulsory, etc., but it had been shown in Philadelphia and elsewhere that notification was not practicable and could not be enforced at present. He had been a member of the Board of Health for eight years. Three years ago the venereal diseases were placed on the list of notifiable complaints, but it soon became apparent that neither the public nor the physicians, more particularly the urologists, were in sympathy with the plan and therefore it was almost totally disregarded. There was, however, a small class of cases to which Dr. Satterthwaite had incidentally referred, in which this regulation had worked well, namely, the class composed of those who were refractory and would not remain under treatment until cured. These cases were reported to the chief medical inspector, Dr. Cairns, who insisted that they either return to their medical adviser or be sent to an institution. This was good so far as it went, but it did not meet the main problem of venereal disease prevention. As Dr. Satterthwaite had intimated, public prostitution was the greatest danger and it had to be controlled by law enforced by the military and civic authorities. The medical profession, however, had a clear and patriotic duty to perform and the same was true of medical bodies such as the American Therapeutic Society, for they should instruct not only the public but military and civic authorities in this class of complaints and how best to accomplish their prophylaxis. The general public was not sufficiently informed in regard to the prevalence and the grave, far-reaching dangers of these loathsome affections, and this information should be spread not only by the medical profession but by military officials and the boards of health. The latter had been carrying on a pretty active propaganda along this line, but unfortunately this reached mostly the medical profession. Dr. Anders said he strongly favored the teaching of sex hygiene in the schools and colleges, and this instruction should include emphasis on chastity upon which Dr. Satterthwaite had insisted. The general public should be impressed with the fact that chastity is not hurtful to either man or woman. That was an aspect of the subject which had been sadly neglected in the past. Men very often exposed themselves to risk through ignorance, and it would seem that the medical profession was somewhat at fault in not having sufficiently emphasized the importance of chastity among young unmarried men. He felt that as individuals and as an organization it was their duty to speak frankly to the public and inform them of these facts and of the great prevalence and far-reaching dangers to life in connection with venereal infection. As Dr. Satterthwaite had said, there was in London a society for the prevention of venereal disease. That society did not attach much influence to moral suasion, but it did insist that all who would persist in exposing themselves to risk should purchase, carry, and use a simple disinfectant which had been found to be efficient in warding off venereal infection. There could be but one opinion on that point, namely, that the advocacy of such methods must encourage rather than diminish prostitution. Dr. Satterthwaite had dealt with the subject in a very masterful fashion and the paper deserved to be widely circulated and appreciated.

Dr. SPENCER L. DAWES of New York said that Dr. Satterthwaite's presentation of the great dangers in public prostitution and also of the prevalence of venereal disease among aliens had impressed him very forcibly, and it might interest the society to hear a statement regarding these two points as related to the hospitals for the insane in the state of New York. It was a very remarkable fact that the greatest ratio of general paresis in the state hospitals in New York today was found among the Italians, and greater among women than among men. That was a very appalling and dreadful statement to make, but in a way it could be explained. There had never been a record anywhere of such a rapid syphilization of a race as among the Italians coming to this country, and it was because of the fact that so many of the Italian men came to this country alone, without their wives and without their sweethearts; they stayed for a time and were exposed to public prostitution, and contracted syphilis, and then later sent for their wives and sweethearts and conveyed the disease to them, and in that way we had the spread of the disease, the incubus falling upon the Italian women.

Dr. JACOB DINER of New York said that the subject presented by Dr. Satterthwaite was of equal importance to that of alcohol, if not greater, and he thoroughly agreed with Dr. Satterthwaite and Dr. Anders that it was primarily a matter of education. He desired, however, to emphasize the fact that education should be spread in a broader way even than through the physician, though his influence was necessarily great. We were living in an era of readjustment, in an era of

strife for the single standard. He thoroughly approved of the single standard, but not in the sense in which that was being taken today, of the low standard of the male, but rather of the high standard previously held for the female. Our progressive women of today demanded equal rights with the male. He would prefer to see the restrictions applied to men as they had been applied to women in the matter of sex relations. When a young woman of today selected her life partner, it was not a question of what his previous moral life had been nor what his present physical condition was, but whether he would be able to support her in the style she had been accustomed to at home; that seemed to be the only determining factor in the eligibility of the man. The idea might seem utopian, but he believed that the eligibility of the male should be the same as that of the female, in the chastity and purity and moral character which he brought into the home.

Dr. BEVERLEY R. TUCKER of Richmond, Va., said that he had been asked by Dr. Satterthwaite to discuss the paper, and expressed his accord with the remarks of Dr. Anders. He felt that chastity was an ideal which would not be reached in the present generation although it should be the goal aimed for, but we had to get down to something more concrete and practical if we proposed in any way to solve or help solve the question today. In Richmond they have had very efficient city health regulations, and venereal diseases were reportable by name or number; the physicians could keep the names confidential. Those infected had to stay under treatment until three negative smears were made in gonorrheal cases or until two negative Wassermann tests were made in syphilis. The physicians had responded very satisfactorily to this plan, and the cases which did not return to the physicians were taken up by the city and treated at the public clinic or in the city hospital under restrictions, or in the city jail under arrest. In that way the majority of the cases had been gotten under control. An infected man was asked to tell where he got his infection, if he could. If he did not know, he was excusable, but most of them would tell. Sometimes several men would report on the same female, and then she was located and taken in charge. Of course the plan did not work perfectly, but it had lessened very greatly the prevalence of venereal disease in Richmond, where a third of the population were negroes who were very hard to manage under this regime, for very few of them went to a physician. They did not seem to have the disease in a very virulent form, either in the early stages or in the late nerve manifestations.

Dr. JOHN TRAVERS of Baltimore said that the admirable paper of Dr. Satterthwaite was well worth remembering. As a ship surgeon during the war, his own records bore out the statements that had been made. He had been on a U. S. transport taking the troops over and bringing them back, and the percentage of cases of venereal disease in the beginning of the service was over 40 per cent. Whenever they stopped at St. Nazaire or other port abroad, on the return trip, the percentage increased, even among the crew, to 75 or 78. On the last trip, after the armistice was signed, a lot of engineers was brought back and the percentage was something like 92 per cent.

Dr. HYMAN I. GOLDSTEIN of Camden, N. J., said that if the plan of reporting these cases was adopted, complete reports should be made. If they were going to be used for statistical or other purposes the job should be done completely or not at all. Various laws had been prepared and passed for more or less indirect methods of reporting venereal disease, and in many instances they had proved to be more or less of a failure. To illustrate concretely what he meant, he stated that several years ago in the state of New Jersey a bill was passed making syphilis and gonorrhea reportable diseases, to be reported in full—name, address, place of occupation, and if possible the source of the infection. Not long after the passage of this bill he went into an ice cream saloon, and serving the customers was a man with typical secondary lesions on his face, a mucous patch in the mouth and angle of the lips, and lesions on the hands. Dr. Goldstein said he asked the man if he was under treatment and whether he knew that he had a contagious disease, and advised him to see a physician. He then reported the case to the State Department of Health as he was required to do under the law, but nothing further was done. It was impossible to say how many cases of venereal disease that a single patient caused. In another instance, a married man (early marriage did not necessarily prevent the spread of disease and it was principally an economic question) who gave a history of having had a sore throat for two months, and some pain in the chest. He was told to strip, which he very reluctantly and hesitatingly did. He was a well-known business man and had a family of five or six children. However, he stripped to the waist, and on assuming a certain position a faint macular rash was noted under the surface of the skin. With considerable hesitation the man then permitted a further examination and an active initial (genital) lesion was found. Upon being asked how long this had existed, he replied for six or seven weeks, and that he was under the care of two physicians. Dr. Goldstein said that his object in speaking of this case was to show that it was sometimes a question for the physician himself. There was little doubt but that this man had infected some member of his family and the physicians were directly responsible. The Wassermann blood tests were strongly positive, of course. The dark field examination and blood Wassermann tests were not made by the previous medical attendants. The matter, however, narrowed itself down to the practical question of how to handle the subject now. The ideal way, as outlined by the speaker, was certainly the preferable way, but this would take time. His own opinion was that a physician was not opposing the prevention of venereal disease by recommending prophylactic treatment to patients who would not follow out the ideal instructions. He also felt that the reporting of these cases, as was done in New Jersey, was a good thing, but that it should be done thoroughly by all physicians and hospitals. It was a very important economic question. When the necessities of life became cheaper and living conditions were changed and readjusted, the young people might mate sooner, and this would tend to reduce the number of infections, but the main point now was for the doctors to make prompt, careful, and early diagnoses, to advise strongly against extramarital and illicit exposure, and where necessary, to give the information pertaining to prophylactic treatment as has been recommended and carried out in the United States Army and Navy.

Dr. SATTERTHWAITE said, in closing, that mistakes were often made in the diagnosis of syphilis. One of the members present, had a case of aortic disease which he had seen with him in consultation. The possibility of its causation being due to syphilis had not been broached. Later Wassermann tests proved that lues existed. Another of the members had transferred to him for a cardiac lesion, an old lady, a spinster, and well connected. On admission to the hospital a diagnosis of tertiary syphilis was made immediately, by the examining physician. In the rural districts of this country, especially, syphilis was apt to be overlooked by the general practitioner, who often had seen so little of the disease that he did not know its phases. Syphilis existed, he could safely say, in at least one-tenth of our population. In cities and congested localities, the incidence was very much greater, of course. As for the efficacy of quarantine in the matter of public prostitution in military circles, he read a cutting from the *New York Medical Journal* of the fortnight previous, in which a statement was made that under the direction of our Surgeon General, it was tried in a group of about 12,000 men, and following it the incidence was reduced about 50 per cent. This incident confirmed what he had said in his paper, that quarantine in military circles could accomplish a great deal. But what we had to do in the future was to protect both men and women by law. If a man or woman contracted the disease and communicated it to his or her consort, it should be a legal matter. We would probably come to that very soon. He would add a few words about the poor prostitutes. The general idea was that they were purely mercenary women. As a matter of fact, however, there had been many cases, especially abroad, since the war, where women had been forced into prostitution from hunger or destitution. Another point he would make was that these women were not always treated properly

in civil life. It had been intimated in print that public venereal clinics were sometimes conducted in so careless and slovenly a manner, as to suggest that healthy persons, especially women, who happened to be suspected of venereal infection, might actually become infected in the clinics.

Some Practical Observations on Glandular Therapy.—Dr. JAMES M. ANDERS of Philadelphia read this paper. (See page 314.)

Therapeutic Uses of Pituitary Gland Substance.—Dr. BEVERLEY R. TUCKER, of Richmond, Va., presented a communication with this title. (See page 316.)

Dr. OLIVER T. OSBORNE of New Haven said the subject of the physiology of the endocrine glands and of the symptoms of their pathology, and the therapeutic value of their extracts was of so much importance and created so much interest, that very much had been written and said with too much enthusiasm and without scientific proof. There was no question that the child, man, or woman was physically and mentally what the secretions of his or her endocrine glands determined. It had been clinically and experimentally demonstrated that the secretions of some, at least, of the endocrine glands were essential for the human being to be normal. However, physicians and even the laity were unfortunately becoming over-enthusiastic in the use of glandular extracts and of glandular mixtures, concerning the activities of which they knew but little, and even patent medicine advertisements were now lauding the use of monkey or other gland materials. Before deciding that a glandular extract was indicated, one must investigate the whole life history of the individual, noting development in all its details from babyhood, through childhood, puberty, and adult life, to the changes from forty-five to fifty, and to senility. The hair, the teeth, the nails, the skin pigmentations, mental activity, the digestion, the blood-pressure, and the character of the circulation all would give indications of the sufficiency or insufficiency of one or more glands. It should also be recognized that the glandular functions were interlocking, and deficiency of one gland might cause deficiencies or hypersecretions of other glands, and the symptoms or conditions present were the outcome of these several disturbed functions. Therefore, to administer empirically a single, or several glandular extracts to a patient, without the most careful supervision or without the understanding that undesired activities might be developed, was inexcusable. On the other hand, from the very nature of these glandular tissues and the fact that the laboratory, even by extirpation, could not always develop positive chemical or hormone values of the glands, necessitated well directed clinical studies. In other words, many of the valued uses of these extracts had been discovered by clinical trials. The endocrine glands that had been proved to have positive therapeutic value were the thyroid, parathyroid, pituitary, suprarenal, and corpus luteum. Other glands that had therapeutic values, which, however, were not so generally recognized or accepted, were the ovaries, testicles, and mammary. All of the other several endocrine gland and organ extracts were as yet subject to a longer clinical proof before they could be accepted as meeting definite indications in the treatment of diseased or disturbed conditions. The pituitary gland was primarily of more importance to the female than to the male, while the suprarenal glands were primarily of more importance to the male than to the female. The pituitary, in conjunction with the thyroid, increased in size and hypersecreted just before, or during the first part of menstruation, and some of the headache of women at these times was due to the congestion of the pituitary gland. As the speaker had pointed out very many years ago, the first, so far as he was acquainted with the early literature, mammary gland extracts when fed to young girls who flooded at their menstrual periods or who menstruated too frequently would inhibit this condition. He also pointed out many years ago that the disturbances of the menopause were largely due to disturbances of the glandular secretions, and that if the thyroid ceased its periodic increased activity at the time the ovarian glands diminished their activity, the hot flashes, nervous disturbances, palpitations, etc., would not occur. On the other hand, if the thyroid diminished its activity too rapidly or too completely, the woman rapidly added weight and showed other signs of hypothyroidism. Thyroid treatment was needed when these latter symptoms were present. Sometimes there was a decided loss of tone in women at this period in which ovarian substance frequently acted as a stimulant and was beneficial. Also ovarian extracts were of value at any period when menstruation was scanty or occurred only at long intervals. The corpus luteum was certainly a distinct gland although it was located in the ovary. It was a stimulant to the uterus and caused its mucous membrane to become ready for pregnancy, or if conception did not occur, allowed the usual uterine flow. Although this gland was frequently administered with success in amenorrhea, he did not believe that it caused ovulation and consequent menstruation, but it did cause the uterus to be ready to bleed. This gland was enlarged and theoretically should be doing more physiological work during the first three months of pregnancy, although the woman normally did not menstruate. Its secretion might be the stimulant that caused the placenta to grow properly. Corpus luteum had been frequently administered for the high blood-pressure that occurred in women at the time of the menopause, and with some success; but it was a potent glandular substance, and might lower the blood-pressure more than was desired. In other words, one must watch the results with corpus luteum administration as carefully as with thyroid. During periods of amenorrhea, or at the time of the menopause, or perhaps some time later, pigmentations were likely to occur, forgotten freckles became prominent, and moles developed. These seemed to evidence a disturbed adrenal secretion, probably of the medullary portion of the adrenals. At present the speaker was studying clinically the activity of extracts from the cortical portion and extracts from the medullary portion of the adrenal glands. But administering the substance as a whole would not only many times stop this tendency to pigmentation and clear up brown spots, but would also cause improvement in the circulation, when there was low blood-pressure. Finally, he would be very careful in polyglandular therapy, much as we should be careful in advising or using polyvaccines.

Dr. CHARLES E. DE M. SAJOUS of Philadelphia said that he could emphatically subscribe to what had been said about the empirical use of organic products. Only recently he had seen a New York lady, whom he referred to Dr. Satterthwaite. Although a very bad case of mitral disorder, she had been given thyroid by a physician previously seen. If persisted in, death would probably have ensued. As consultant of the Bell Telephone Company the speaker had had occasion to see many cases of exophthalmic goiter and hyperthyroidism. In one case with bulging eyes and prominent thyroid, the patient had been seen by fifteen doctors in succession and had been treated for cardiac trouble owing to the arrhythmia; not one had recognized the true condition. Between the promiscuous use of organic products on the one side and the non-recognition of endocrine disorders on the other, much poor work was being done. In respect to pluriglandular therapy, a word of caution was offered in view of the gunshot prescriptions that were being given for various conditions—a renewal, in a measure, of the old polypharmacy methods. The speaker urged that no glandular product should be administered without taking into account what glandular stigmata each case presented. There was no doubt that today the profession possessed a very distinct therapy for all endocrinopathies and the general diseases they complicated; but the syndrome could be detected in each case and there was no reason why pluriglandular treatment should be used unless it was indicated by a pluriglandular syndrome. A feature that had not been referred to was the combination of some gland treatment with the usual remedies, strychnine, digitalis, etc. In cases of secondary anemia, for instance, after finding out the cause and eliminating it, one would obtain better and prompter results by adding a small dose of adrenal gland or posterior pituitary and strychnine to the iron, the constituents of the hemoglobin molecule being thus supplied. Concerning immunology, Dr. Sajous felt that many cases were being sacrificed today because the relationship between the thyroid and the immune chemistry of the body, now fully recognized on the continent of Europe, was neg-

lected. He was confident that if surgeons realized more what the thyroid meant they would not remove thyroids as freely as they did. Medical treatment was slower, but it preserved a defensive organ. Although he treated many such cases he had never had to send one to a surgeon, and had had no deaths so far. Others had obtained similar results. Some of his cured cases had been sorely tried during the war and stood the test without recurrence. One of these patients, a Canadian lady, who had suffered from one of the worst cases of exophthalmic goiter he had ever seen, had had four sons at the front during the entire war and had gone through great anxiety and distress, and yet had remained perfectly well. His treatment, published in the MEDICAL RECORD of September 27, 1919, was based on the recognition of the importance of the relation of the thyroid gland to the immune chemistry of the body. The essential point was to find out what the thyroid gland was fighting and to eliminate it, and to avoid what, to him, was virtually a criminal method, the "symptomatic treatment," carelessly recommended by many authors. As for acromegaly, Dr. Sajous was always ready to yield to *bona fide* evidence, but he had not changed his mind to the effect that the pituitary gland was not a secreting organ, and before very long he would adduce ample evidence to that effect. He had patiently awaited the believers in the secretory theory to prove the existence of a secretion, but it was increasingly becoming evident that the socalled secretion was a myth, as the speaker had long urged. Taking, for instance, the supposed relationship between the anterior pituitary body and growth based upon the prevailing conception of acromegaly: Had any one present ever caused a dwarf to grow by giving him anterior pituitary? Even tethelin had completely failed in this respect. And yet other glandular products had sometimes been found very efficient in this respect when the cause of the arrest of growth could be determined. All were familiar with the connection between pituitary disorders and polyuria, but did they realize that this condition could also be caused by passing a needle into the basal tissues behind the pituitary, cutting off the splanchnic, *i. e.* along the pituitoneural path Dr. Sajous had long ago described? Every one had been dazzled by Cushing's beautiful book, but this brilliant surgeon had not studied phylogeny far back enough or he would have found a close relationship between the sympathetic and the posterior lobe of the pituitary body, which, through the pituitary neural path, influenced the adrenals and other endocrines. The secretory theory had started as a mere assumption and was dying fast—a good riddance which had been misleading able workers for several decades. Dr. Sajous said that if any one had seen his cases of acromegaly when they first came under treatment based upon his conception and two months afterward, they would have been astonished by the change. The faces gradually flattened down as far as the bones would permit. Was it through glandular therapy? No; through vasocontraction. He considered acromegaly as a vasoneurosis due to a lesion of the anterior pituitary capable of inhibiting more or less the coordinating functions of the neural or posterior lobe.

The Treatment of Patients After Certain Abdominal Operations Have Failed.—Dr. W. WAYNE BABCOCK of Philadelphia read this paper. (See page 319.)

Dr. F. M. POTTENGER of Monrovia, Calif., directed attention to one point in regard to pain after diseased conditions had been cleared up, which had not been sufficiently appreciated because our conceptions were anatomical instead of physiological. When an organic lesion was removed, the nerves were not restored to their former power of resisting impulses. Women with uterine troubles, patients with tuberculosis, pleurisy, or chronic appendicitis might be relieved of all these troubles, yet if they should be worried or tired out they would still often have their pains because the threshold of response in the neurons was lowered so that the impulse passed more easily than normal. One might remove the organ or the disease, but the patient's nerves were still not restored to normal.

Dr. HYMAN I. GOLDSTEIN of Camden, N. J., said that in this connection it should be remembered that some very good surgeons were too apt to accept the diagnosis made by referring physicians. In some of these cases, were the surgeon and staff to reexamine the patients more thoroughly, some of these operative failures might be avoided. He then cited a case with attacks similar to those mentioned by Dr. Babcock, with acute indications and symptoms such as vomiting, epigastric pain, etc. After thorough Roentgenographic study the patient was operated upon under the suspicion of possible ulcer, but no ulcer was found, nor anything abnormal; the usual procedure of appendectomy was followed, and the patient felt a little better for a time. Four to six weeks later he again had severe vomiting and epigastric pain. The blood Wassermann was negative and there was no history of any initial lesion. Later the pains became worse, and it was decided that possibly he had adhesions following the first operation. He was again subjected to operation and nothing seriously abnormal was found. Subsequently the spinal fluid and blood Wassermann was found to be strongly positive. In the meantime the patient had had several of these seizures. After the second injection of neoarsphenamine the man, for the first time in eight years, had no seizures, and further treatment practically cured him.

Dr. FUSSELL of Philadelphia reported two cases of acute pericarditis which simulated acute appendicitis, at a recent (May 30, 1921) meeting of the College of Physicians of Philadelphia, section on General Medicine. Some years ago Dr. Libman of New York City reported cases of primary sarcoma of the intestines, simulating appendicitis, while last year the speaker reported a case of primary sarcoma of the appendix with intestinal obstruction by a band that simulated acute appendicitis.

(*To be continued.*)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 5, 1921.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Neurology.

Bradykinetic Analysis by Means of Ultrarapid Photography.—Dr. S. PHILIP GOODHART gave a lantern slide demonstration, which emphasized the value of ultrarapid photography in the study of various neurological conditions affecting motor function.

The Production of Hallucinatory Phenomena.—Dr. MORTON PRINCE of Boston made this presentation. He said the paper should be called "The Pathological Mechanism of Hallucination as Based upon Experimental Studies." The convential theories of traditional psychiatry regarded the mechanism of hallucinations as belonging to one or the other of two classes, namely, the anatomical-physiological theories and the psychic theories. All the anatomical-physiological theories brought forward by Schroeder, Kraft-Ebing, Joley, etc., were but variations of one and the same thing. They all postulated a local idealization in the cortex or basal ganglia. The only difference in these theories was that some put the idealization in one part and some in another. On close examination they were all unsatisfactory and failed to explain the content of hallucination, which involved a higher functional process. Turning to the psychological theories, these ascribed hallucinations to a function of the subconscious, but they were rather weak in elucidating the process. Some said it was an expression of a subconscious wish; others that it was a regression to a primary infantile mode of thinking, but they did not explain why the process never emerged into consciousness. Dr. Prince said he was going to approach the question of hallucinations from the psychological point of view. Hallucinations were psychological; at least we had to explain them in psychological terms. Whether we should be able to explain them in anatomical terms was another question; we could not even approximate such an attempt to-day. There were three different modes of approach. (1) By experiment one could induce experimental hallucination in certain people; it was easy to do; it was a common phenomenon. One could produce hallucination by fixation of attention. If certain

persons looked into a glass globe a hallucination would be induced. The globe was not necessary; it was merely necessary to fix the attention, and perhaps suggest that something was going to happen. In that way one could produce hallucination and study its form and structure and draw inferences as to the process involved. The structure and form and behavior of hallucinations in the sane were similar to those in the insane or paranoiac. It happened when a person looked into a glass and his attention was gripped that he acted a part; the hallucination could not be explained except by assuming that there was another process besides his conscious mind that made the kaleidoscopic picture. What was that process that might reproduce memory, imagination, and logic, and might exhibit nearly every faculty of the mind? The hallucination might be a hearing or a visual reproduction. A second mode of attacking the problem was that of hypnosis. By putting a person into a hypnotic state one was able to recover memories of events outside of his conscious recollection, and among those memories were the memories that were stored in the subconscious. The idea had come to him that the problem was why we were not aware of the subconscious. In four cases studied there had been these images which were not in the conscious mind, and those images were of the same nature as those we all had in conscious thought. That was, if one thought of going home and going to bed he immediately had a mental picture of his home and his bed. In certain individuals those images became coconscious images, merged into consciousness, and became hallucinations. Hallucinations were then images of the subconscious and in certain cases emerged into the consciousness. Those images might occur as a posthypnosis phenomenon or they might occur in certain states of exaltation or depression. As an illustration, a widow on the anniversary of her wedding became very much depressed, but was determined to put her depression out of her mind. She did so as she thought. In the evening she sat in the twilight and of a sudden felt something on the other side of the room. Then she had the hallucination that her husband was there surrounded by a blaze of light. Investigation showed that she was getting memories of the past. There was a similar picture in a gilt frame of her husband. This had suddenly emerged and the image was identical with the picture. The question was how to get at the process. Of course one must tap the subconscious. He now had a way of tapping the subconscious, and that was by automatic script. Automatic script was an important means of research and had been much neglected. As a method of research it was comparable to the method of the physicist who studied radioactivity. The physicist did not study atoms directly; he saw only the manifestations and from these he inferred what went on in the atom. Script was writing and it was done by something. Script showed intelligence, logic, imagination. It was done by something, not consciously. If not done consciously, it must be done by something unconscious—the subconscious had been tapped. What was needed then was a subject who could write without being aware of it and one who had hallucinations. Dr. Prince said that if asked how he knew that it was automatic writing, he must say that he did not know that it was automatic. There was a consensus of opinion that epileptic convulsions were not faked, though they might be faked. There were people who wrote automatically and there were scientists who wrote automatically, who were absolutely unaware of what they were writing. That had to be assumed as the basis of the experiment. Then the person had to have hallucinations and the question was what relation the hallucinations had to the script. Dr. Prince then explained that the subject had her head covered with a cloth and was directed to write. When she began to have an hallucination it was to be marked on the script and then when the hallucination disappeared it was again to be noted on the script. A number of charts were shown with the hallucination and script side by side. The substance of the hallucination and that of the script was the same, making it evident that the subconscious had been tapped. Another experiment was carried out by taking an individual with a double personality who was asked to review an episode in the past life of one of the personalities. She at the same time wrote and the script ran parallel to the episode related. If the script thus tapped the unconscious and was correlated with hallucination, by script one might reach the hallucination which occurred in certain psychoses. The application might be left to the psychiatrist. As to the mechanism of the process, testimony indicated that these thoughts were below the subconscious level. The thoughts formed themselves and made images, that was to say, those objects were visualized just as events were visualized in the conscious mind. After a few moments the image that had been formed merged into consciousness and produced hallucination. This theory was in harmony with other processes of investigation, namely when a certain hallucination occurred similar to those seen in the insane, the hallucination was caused by the breaking out of an ordinary imagery, which in these cases was subconscious. When an hallucination occurred it was a provisional hypothesis that a larger process was going on below the conscious level and the hallucination was a signal flag of danger of what was going on below. Therefore, if we wanted a real explanation we must look into the underlying processes. There was in this theory a distinct divergence from the theory of Freud. Hallucinations were due to a subconscious process, perhaps such as he had pictured, but they were not a regression to an infantile type before language had been acquired. This was anything but a regression; it was a highly developed process representing the imagery of thought. Instead of a wish fulfillment it was the wish itself. This was not the whole problem of hallucination, it was only the mechanism; there remained why we had subconscious processes, and why we did not have subconscious processes projecting hallucinations into our minds all the time.

Dr. JOHN T. MACCURDY said that in view of the lateness of the hour he thought it would be a finer compliment to Dr. Prince merely to move a vote of thanks than to attempt to discuss his address. He would say, however, that this was one of the best pieces of work Dr. Prince had done and he knew of no higher comparison. The problem of hallucination was one that had never been taken up seriously from the standpoint of the mechanism of the mind. This was really the first attempt to trace out the way false sense perceptions were obtruded upon the consciousness.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DIE GESCHLECHTSKALTE DER FRAU. By Dr. WILHELM STEKEL. 490 pages. Price 96 marks. Published by Urban & Schwarzenberg, Berlin and Vienna.

DISEASES OF CHILDREN. By HERMAN B. SHEFFIELD, M.D. 798 pages with 238 illustrations. Price, $9.00. Published by C. V. Mosby Company, St. Louis.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints Volume xxxvii. 613 pages with illustrations. Published by The Rockefeller Institute for Medical Research, New York.

INFORME DEL DIRECTOR DE SANIDAD NACIONAL. Correspondiente al año de 1920. 382 pages. Published by F. J. Camejo & Co., Caracas.

LES EXTRAITS HYPOPHYSAIRES. Par le Dr. LÉON POULIOT. 94 pages. Price, five francs. Published by L'Expansion Scientifique Française, Paris.

NACHKRANKHEITEN DER RUHR. By Prof. Dr. H. STRAUB. 61 pages. Price, seven marks. Published by Carl Marhold, Halle a. S.

UBER DAS SCHICKSAL DER KRIEGSBLINDEN UND IHRE VERSORGUNG. Von Dr. KURT UHTHOFF. 100 pages. Price, 9.50 marks. Published by Carl Marhold, Halle a. S.

LEHRBUCH DER LUNGENKRANKHEITEN. Von Dr. ADOLPH BACMEISTER. 399 pages with illustrations. Price, 126 marks. Published by Georg Thieme, Leipzig.

Miscellany.

Infinitesimals in Medicine.—Dejust has recently published in the *Revue scientifique* an article which is reviewed in *La Presse Médicale* for June 11, 1921, xxix, 47. He first narrates the Hahnemannian conceptions of "similia" and infinitesimal dosage and then adds documents obtained along the lines of general science. The first is the work of Peyraud which was submitted to the Academy of Medicine. It comprises two sets of animal experiments in one of which attempts were made to immunize against tetanus with strychnine, or, in other words, to vaccinate against tetanus by the use of that alkaloid. The other series had to do with certain similarities between rabies and poisoning with the essential oil of tansy, which led to the use of the latter in immunizing against rabies. The experiments were criticized and control experiments were made, the whole subject being far from settled. The subject of minute dosage of drugs is next covered and while certain substances can exhibit activity in extreme attenuation—the author cites many examples—nothing has been discovered in the laboratories to suggest that drugs can be activated by succussion or that subdivision carried on indefinitely can release new forms of drug energy. Activity in a state of minute subdivision is inherent in the particular drug and not determined by outside manipulation. The author suggests that future work should be undertaken *de novo* without any attempt to build on the old superstructure, and commends the work of Peyraud, Rabe, and Hirschland, in which strict laboratory technique is applied to the two underlying problems of similia and infinitesimals.

Max Nordau, Physician, Sociologist, and Philosopher.—*La Medicina Ibera* for May 21, 1921, xiv, 185, contains a short account of the activities of this well-known writer, as one of a series of contributions on physician-authors. It seems to have appeared originally in another Spanish periodical, the *Revista Americana de Farmacia, Medicina y Hospitales*. Nordau was born in Budapest but was descended from an old Sephardic family of Segovia, Spain, and some of his ancestors actually used the surname of De Segovia. He was taught at home Latin, Greek, Hebrew, and probably the ancient Castillian idiom known as "Chudeo," which is quite intelligible to a Spaniard of today. He went through the University of Budapest, graduating also from its medical department; served as regimental surgeon and traveled extensively, before settling down to practise in his home city. After two years of practice he removed to Paris, where he thenceforth divided his energies between literature and clinical work. The World War found him in a precarious position. In Paris he was suspected of Teutonic sympathies, and in Hungary was held to be pro-Ally. As an asylum in England or Italy was out of the question, he took the only course open to him, and moved to Spain, the home of his ancestors, returning to Paris after the conclusion of the war.

His activities include the publication of four novels and a book of short stories, five dramas, and many essays on art, history, and Jewish interests. In 1905 he was elected president of the Zionist Congress. His fame is due chiefly to his polemical writings in the fields of religion, politics, and economics. He is said to be engaged today in writing what he regards as his masterpiece, the "Essentials of Civilization," in which he appears as a pessimist. The theme is the multiplication of human desires as contrasted with the shortage of supply, which status begets discontent and disintegration. There is but one remedy—gradual education of the masses—which at best can aid only very slightly in the solution. Nordau was one of those who had hoped much from the formation of the League of Nations, and the repudiation of the latter by America has probably contributed to his pessimism.

The Peking Union Medical College, situated in the capital of the Chinese Republic, had its beginning in an earlier institution, the Union Medical College, founded in 1906 by the joint efforts of six British and American missionary societies. The property of the earlier school was transferred in 1916 to the China Medical Board of the Rockefeller Foundation, which has purchased additional land and erected, in an interesting adaptation of classic Chinese architecture, a series of hospital and laboratory buildings. The institution comprises not only the medical school, but also a 250-bed hospital with outpatient clinics, a nurse training school, and a premedical school—an institution of junior college grade with a distinct faculty and group of laboratory and classroom buildings. The new buildings will be dedicated the latter part of September, the ceremonies filling the week of the 15th to 22d of that month.

Crumbs Wanted for the Brain Worker.—The editor of *La Presse Médicale* has a short editorial on this subject in the May 25, 1921, edition of his journal (xxix, 42). Recently one of the Cabinet—it matters not which one in these times of rapid turnover of ministries—made a pathetic appeal for the brain worker, through Parliament, to the rich commercialists and industrialists. He reminded them that their wealth came in a measure from the contributions to science made by the laboratory man, whose discoveries were ever revolutionizing commerce, agriculture, and manufactures. The big men of the country did indeed recognize the laboratory as a source of wealth and acted by supporting it, but the laboratory worker himself received only a meager salary. Crœsus has added greatly to his wealth through the same war activities which left the laboratory men hardly able to exist. The appeal was eloquent and unanswerable by critics, but will it be heard? To visualize the situation will the high-brow scientist get the crumbs which remain after Crœsus has banqueted? Meanwhile the burdens of taxation continue to accumulate. Cannot Crœsus emulate the beekeeper who keeps back enough honey to nourish the bees which support and enrich him? The state takes care more and more of its helpless classes—of those who cannot contribute to its wealth, but does nothing for its highest types of producers of wealth. The result is easily foreseen, for the laboratory man will some day give up in disgust, no one will be found to replace him, the laboratories will close, and wealth will soon feel the results of this suppression, while the whole commonwealth will face ruin.

REMARKS ON ORTHOPEDIC TREATMENTS IN CHRONIC AND SEVERE NERVOUS DISEASES.

A PLEA FOR MORE FREQUENT APPLICATION OF ORTHOPEDIC METHODS IN NEUROLOGICAL CASES.*

BY SAMUEL W. BOORSTEIN, M.D.,

NEW YORK.

INSTRUCTOR IN ORTHOPEDIC SURGERY, FORDHAM UNIVERSITY MEDICAL SCHOOL; ADJUNCT VISITING ORTHOPEDIC SURGEON, MONTEFIORE HOSPITAL; NEUROLOGICAL-ORTHOPEDIC SURGEON, CENTRAL NEUROLOGICAL HOSPITAL; CHIEF OF ORTHOPEDIC DEPARTMENT, FORDHAM HOSPITAL, O. P. D.; ASSISTANT VISITING SURGEON, FORDHAM HOSPITAL.

IT is well known that Montefiore Hospital is an institution for Chronic Diseases and the class of cases that are admitted there. There are other similar institutions in the U. S., though not so well known. Many physicians have no doubt referred patients to such institutions with the distinct conviction that the latter would stay there forever. They even thanked the Almighty that such institutions do exist to relieve the physicians from troublesome and nerve-racking chronic cases. Still to the great astonishment of these medical men some of the hopelessly doomed patients have appeared after a time, at their offices, walking even without a cane as if returning from the grave. Their surprising resurrection was for the family physician a reminder of his failures and of the success of the "Hospital." It may be worth while to demonstrate how these achievements are attained. The methods used are so simple that everyone can follow them. The writer believes that the methods employed in Montefiore Hospital, of which he has had ample experience, will prove beneficial if employed by others.

It is not necessary to discuss the treatments used in chronic arthritis as our studies and results have been amply published. Nor is it desirable to take up the cardiacs or the tuberculous, but the paper will be limited to the more difficult types, *i. e.*, the neurological cases. It is self-evident that an institution of this nature does not get the early cases or the light ones as these patients visit the dispensaries or the private physicians. It is only after they become bedridden that they are referred to a hospital for chronic diseases.

As soon as they are admitted, careful examinations are made by the neurological men who are "pains-takers" with their charts and graphic recordings. The laboratory and *x*-ray findings are then done. Finally the disease is labelled. For illustration, it may be said that the chronic affliction is a tumor of the cord or a transverse myelitis or peripheral neuritis or multiple sclerosis or cerebro-spinal lues. If an operation is decided upon, it is performed and the after treatments are begun immediately after the operation. If no operation is deemed necessary or if an operation has already been done without success, the patients are immediately after examination referred to their proper departments.

Just as in modern treatment of fractures, the pendulum has swung from complete rest or immobilization to early exercises and mobilization, so with neurological cases the pendulum has swung from "rest" which they have enjoyed enough to their regret prior to admission to such an institution, to mobility and activity. Only occasionally is a little rest permitted in intervals. The principle is: "There is a time for rest and a time for activity, the second one is the more useful."

The treatments of course include medications, salvarsan, sodium cacodylate, other injections, etc., but the main work is left to the orthopedic surgeon. He is called upon to take charge of the neuromuscular system. After all, one has to remember that the vast majority of disabled and crippled have some trouble with their neuromuscular system rather than the skeleton or osseous. As a matter of fact, Andry, the founder of orthopedics, attributed all deformities to muscular deficiencies. The physiotherapeutic department is therefore under the care of the orthopedic surgeon. The important work is how to make these patients walk or use their upper extremities.

In this respect Montefiore Hospital can justly claim more success than other institutions of similar character. Many methods have been used which have produced excellent results. Even the purely hysterical and neurasthenic patients are treated as real disabled. (The patients are not told that they are hysterical.) Most of the patients are not able to walk for the reason that the articular sense is gone, through either organic or functional changes. Some are afraid to walk, as they have no correct perception where their limbs are. Very often the limbs bend under them as in tabes, or the motor muscles do not respond to the order given by the brain, as in anterior poliomyelitis or transverse myelitis, or the spasms prevent free use of the muscles as in spastic paralysis. The weak limb is therefore encased in a plaster splint, either including the foot or not, extending to the groin. The patient is instructed in the proper way of getting up, of standing, of walking, and particularly, the proper way of using the crutches. Very few people

*From the Orthopedic Service of the Montefiore Hospital. Read before Bronx County Medical Society, June 16, 1920, at the meeting in the Montefiore Hospital.

know how to use crutches and very few physicians instruct their patients exactly how to use them; perhaps they have never been instructed themselves. The patient therefore fails on the first attempt and does not try any more. (This statement does not refer to purely functional cases; the fact is, that even in organic cases their first failure discourages further attempts.)

If the first attempt is successful, the results aimed at are assured. After a while the plaster splints are substituted by removable ones. Then one crutch is taken away and proper instruction is given how to use the remaining crutch. Then the crutch is exchanged for a cane. Sometimes the splints can be left off at this stage, but in most of the cases braces are necessary. The other treatments are of course kept up all the time. From discarding the cane to a walk in a nearby park, or an extensive trip is only a question of weeks.

What Is the Principle of the Plaster Splints Applied to the Feet or Back?—The patient cannot stand up or walk for one of the four reasons: (1) There may be flaccid paralysis, *i.e.* when walking is slow, steps shortened and legs dragged. This gait is found in anterior poliomyelitis, polyneuritis, diphtheritic paralysis, and muscular atrophies. (2) There may be spastic gait in which the patient walks with small, leaping steps, knees held stiff, feet in plantar flexion, and toes tending to stick to the floor. This gait is found in organic hemiplegia, cerebral diplegia, multiple sclerosis, and tumor of the cord. (3) The ataxic gait, found in tabes, Friedreich's ataxia and dystonia. (4) The abnormal gaits found in hysterical or neurasthenic patients.

Naturally many patients cannot walk on account of deformities and contractures present. It is self-evident that all contractures should be prevented, and, if present, should be corrected by proper orthopedic methods, the details of which need not be discussed in this paper. Nor is it necessary to discuss just now any orthopedic operation such as tendon transplantation, arthrodesis, Stoffel's operation, tendon fixation, etc., which the reader can find in any orthopedic treatise.

(*A*) *Plaster Splints in Flaccid Paralysis.*—Assuming that the deformities have been corrected, the patient may still not be able to walk because there is weakness of the muscles holding the balance. Is there any better method than to put the limb in the proper position and substitute an artificial support for the natural one which has failed? The orthopedic surgeon uses this method freely in the anterior poliomyelitic cases with his braces. It takes, however, a long time to get braces and the muscles may atrophy meanwhile. Plaster splints are usually applied while waiting for the braces. In the case of chronic patients, many of them had probably, previous to their admission, braces that were improperly fitted and they have no more confidence in them. The plaster splints are therefore applied and the proper use of the limbs is encouraged.

In this group are included the cases of paralysis due to transverse myelitis and nerve palsies, also functional paralysis where it is absolutely necessary to help the proper use of the limbs. The patient uses the limbs without knowing whether the muscles hold the position by their own power or whether the plaster splints prevent the bending of the limbs.

Lovett[5], in a very interesting article, demonstrates that even patients with complete flaccid paralysis of both lower extremities can walk. He sounds an encouraging note in these cases. We have had similar good results. About the splints he states: "If the knees are prevented from flexing by splints, the erect position can be maintained without crutches only if the gluteus maximus muscles are strong enough to hold the trunk from falling forward. The loss of the gluteus maximus can, however, be compensated for by a peculiar method of using the crutches for what may be called 'tripod' walking."

Another proper use of crutches in a method slightly different from Lovett's will be described in this paper.

It may be of interest to describe here three interesting cases for illustration:

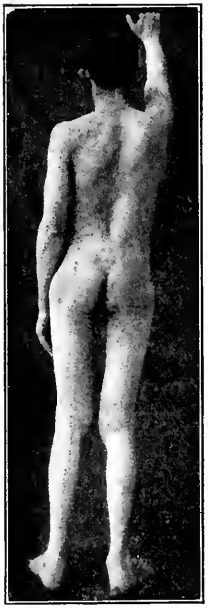

Fig. 1—I. G. G. Case No. 3, showing proper posture and fair musculature of body and feet. See absence of gibbus on spine.

Case I.—A. H., a man with peripheral neuritis (either alcoholic or lead) was in the Home for a year and a half receiving massage and exercises in bed. The muscle had improved. There was good power in the quadriceps, glutei, and dorsal flexors of the feet, still the man has made no attempt to walk. During the ward rounds one day he was told by the attending orthopedist that he could walk in from two to three days if he wanted, to which he consented. Plaster splints to both knees were applied so as to give him stability. The next day he was shown the proper method of using the crutches and he began to walk immediately. In four weeks he threw away the plasters and walked with one cane. In six weeks he returned to his occupation as painter, though his hands were somewhat weak.

Case II.—This was one of a young girl of twenty (Hannah B.), who had a marked tremor in both ankles resembling "shimmi" dancing. The diagnosis of the neurologists was "neurasthenia." Strapping of both ankles with red flannel bandages (for psychic effect),

but with several layers of strong adhesive plaster for real support, gave her confidence. She walked immediately, even without crutches, and was discharged in six weeks.

CASE III.—Isidore G., male, aged twenty-three, had traumatic myelitis following a crushed fracture of last

FIG. 2—A case with left hemiplegia showing contraction of hand before application of plaster splints.

dorsal and first lumbar vertebræ, resulting in paralysis of both lower extremities, loss of bladder and rectal control. Was operated on by Dr. A. S. Taylor in another institution in May, 1918 (eight months after the accident), when a laminectomy was performed. The rectal and bladder condition improved somewhat, but the patient was unable to walk. He was admitted to Montefiore Hospital in September, 1918, one year after the accident. He was treated with massage and exercises, etc., but was still confined to the chair. Physical examination in March, 1919, showed fair power in the glutei and quadriceps, weak power in the dorsal flexors of the foot. Plaster splints, extending from the toes to the groin, were then applied and he was put up on his feet in one week. At present the patient walks with one cane only and uses braces. (Fig. 1.)

This patient demonstrates that operation without after-treatments will not result in marked improvement, and unless the patient is supported by splints very early (to be changed later on for braces) he will never begin to walk no matter how much improvement in the muscular power is obtained.

It is probably best that the plaster splints should be applied while the patient is still on the operating table. As soon as it is safe to permit the patient to stand, he should do so while he has the first casts. He will feel safe and the physical influence of the operation will encourage him to walk.

(*B*) *Splints in Spastic Paralysis.*—In the second type, *i.e.* spastic paraplegia where there is present involuntary contractures due to motor irritation, either through increased physiological stimuli, or through pathological irritation of the motor neuron system, the plaster splints are of extreme value. They control the tremors.

It was Sherrington[4] who was able to prove "that a constant stream of messages arises in the contracting extensors of the knee and, passing to the cells which control the action of the hamstrings, exercises on them a regulating influence. In this way a balance is maintained between the degree of shortening of the extensors of the knee and the degree of lengthening of the hamstring flexors. Similarly, messages are being produced in the hamstring muscles which exercise a regulating or inhibitive influence over the extensor motor cells. Thus the state or degree of contraction in any muscle is regulated in the main by two sets of stimuli or messages: (1) Those arising in its own fibers; (2) Those arising in the fibers of its opponent. The more nearly we can place muscles in a state of rest, the less call will there be in this reflex mechanism."

In spastic paralysis, particularly in infantile paraplegias, there is a disturbance of the balance in the antagonistic action of the spinal and cerebral innervation of the muscles. According to Freund, rigidity occurs when the function of the cortical neuron is merely weakened but not lost (Lorenz[5]).

Hilton[6] also stated distinctly in considering a similar affliction, "that if he could keep the joint at rest and thus arrest the production of painful articular stimuli within the knee-joint in arthritis, he would succeed in allaying the contracted state of the muscles of the thigh. We have to arrest or diminish the transmission of stimuli."

The plaster splint is, therefore, the best ideal for that desired rest to arrest and diminish the production of stimuli and overcome the disturbance of balance in the muscular antagonisms.

Lorenz[5] says in this connection: "The method to be chosen to obtain this is to reduce the unrestrained part of the muscles which cause the contracture to a degree that will permit of their properly balanced antagonism working in unison with those muscles of less spastic power which are situated in the opposite side of the deformity. If this object is properly secured, a muscle may still contract spasmodically, as it did before, but the effect of this undesirable contraction will be diminished to such an extent as to be balanced by the antagonists while still permitting of locomotion. We arrive at this by simple tenotomy or myorrhexis of the muscles producing the contracture. The contracture is overcorrected and retained in plaster for six to eight weeks."

Three illustrative cases will be cited:

CASE IV.—Bernard P., a man of thirty-five, of extreme nervous temperament, who had a severe form of encephalitis lethargica, treated by Dr. I. Abrahamson and the late Dr. H. Climenko, seen by the writer in January, 1920, when he had marked spasticity of both knees, shoulders, and spine with beginning of contractures of knees. He was in bed and could not even raise on a pillow. Splints on his shoulders and on his feet, extending to the groins, were applied. The pain in the knees was severe for two or three days on account of the spasm, but this was gradually diminished. In seven days he was put up on his feet. The splints were removed in four weeks. At present he walks perfectly well. Had he been in bed a few months more the contractures would have been severe, necessitating op-

FIG. 3—Same patient as in Fig 2 showing the relaxation of the hand after the removal of the plaster splint which was on only ten days.

erations. His mental attitude would have been worse and he would not have given the proper help.

CASE V.—Dora P., a woman aged twenty-two, with a left-sided hemiplegia following a confinement. Was in bed six to eight weeks, and had already contractures of knees with drop foot. A plaster splint on foot and

knee gave her stability and she walked the next day with one crutch.

As a matter of fact, all patients with hemiplegia whom I had a chance to see very early have been treated in the same way, *i.e.* application of plaster splints to the knees and hand. Many patients at the Home, who had contractures of the hand following hemiplegia, had a plaster cast applied which was left on for two or three weeks; the spasm was then relaxed and treatments could be instituted. (Figs. 2 and 3.) (For more details, the reader is referred to a former article, "Early Surgical and Orthopedic Treatments of Hemiplegia.")[2]

Is it necessary to put on casts on a patient with hemiplegia whose knee is straight due to hypertonicity of the quadriceps in order to train him to walk? The answer is "yes." The plaster will prevent the hypertonicity and the reflexes of the quadriceps and hamstrings and relax the muscles.

CASE VI.—John McA., male, age forty-six; spastic paraplegia since age of twenty-eight. Was on chair

length and, particularly, the length from the arm rest to the hand rest. A crutch must be 1½ to 2 inches longer than the length from the armpit to the sole of the foot. The distance between arm rest and hand rest must be 2 to 2½ inches less than the actual length between the armpit and palm of the hand. Both rests must be well padded.

The first principle is to instruct the patient not to put his weight on the arm rest but on the hand rest and thus crutch paralysis will be avoided, and train the patient to stand when the crutches are in front of the body as far as possible. He must train himself for a while to stand, as he has probably lost the sense of upright equilibrium.

When starting to walk, both crutches must be in front of the body about four to five inches, or really as far as possible. This gives the "tripod" appearance described by Lovett in his recent article[5]. (Fig. 1.)

Then the patient must bring one crutch a little forward, leaning the entire body to the other side

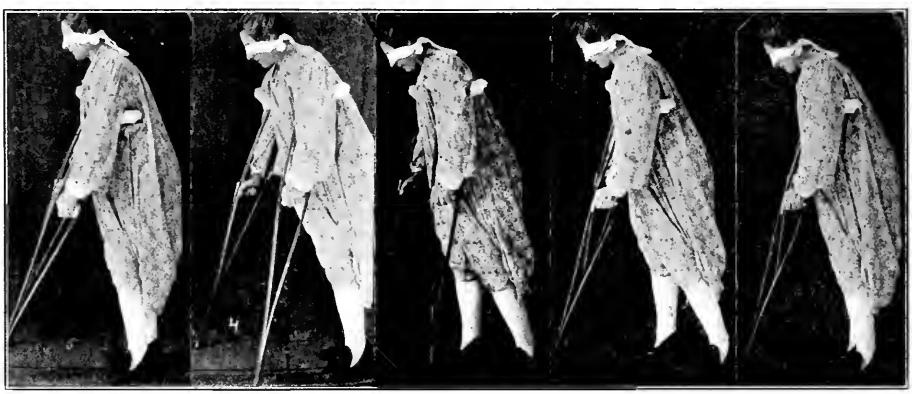

Fig. 4. Fig. 5. Fig. 6. Fig. 7. Fig. 8.

FIG. 4—Proper use of crutches—First step—Both crutches in front of the body, patient leaning on the hand rest. FIG. 5—Second step. Right crutch advanced forward. FIG. 6—Third step. Right foot advanced forward but not enough to touch the crutch. FIG. 7—Fourth step. Left crutch advanced forward in the same line with the right crutch. FIG. 8—Fifth step. Left foot advanced in the same position as the right foot. Notice the distance between the crutches and the feet.

for fourteen years. Physical examination showed marked contracture of tendo Achillis and talipes equinovarus. Simple tenotomy of both Achilles tendons was performed, the feet were corrected, and plaster casts were applied extending to the knees. In a few days the patient showed that he could wiggle with the toes. The second week he was put on his feet and taught how to stand. In the third week the patient was shown how to use the crutches and he began to walk. At present he is still wearing the first casts and the time is thus too short to report any more progress.

(*A*) *Splints in Tabes and Other Ataxic Gaits.*—In tabes the patient does not know the proper position of the limbs; the articular sense is lost, and if he has a cast he feels safe. In him the method is purely psychic. After wearing the cast for a few weeks, Frenkel's treatments are used with great benefit. If a support is to be used for a long time, the splints should be replaced by properly fitted braces.

Methods of Using the Crutches Properly.—When one orders a crutch, he should do the same as he does with a prescription. He must give the proper

(Fig. 2). Then the foot corresponding to the crutch is brought a little forward, but does not come up to the crutch (Fig. 3). Then the other crutch is brought forward while the body leans to the opposite side (Fig. 4). Then the second foot is brought forward (Fig. 5). (The gait is different than the one described by Lovett.) This gait resembles that of a pacing horse. At no time, however, are the crutches in the same line with the body. They must always be in front of the body line. That will prevent the patient from falling and will also help to extend the hips. If the patient cannot advance the foot forward voluntarily as in severe degrees of flaccid paralysis, he usually twists the body a little forward; thus he performs some voluntary movement. By bringing one foot forward at a time he exercises a group in each limb. We had many cases of patients who walked with great difficulty even with crutches. When, however, the proper method of using the crutches was demonstrated to them, they began to walk with great ease. At the Dominion Orthopedic Hospital in Toronto

they use crutches without arm rests, resting on the hand rest and having two cuffs for the arm.

When a single crutch or cane is used the process is performed on the same principle, *i.e.* the order is: the crutch, the corresponding foot, then the other foot. Within a short time the wheel chair is taken away from the patient; thus he must walk to the dining room and visit other wards, etc., while using the crutches. The crutches are also removed earlier than the patient wishes to part with them. The cane, however, is permitted for a long time.

Principle of Exercises.—The value of exercises to prevent deformities is a well established fact. It was still in 1743, when Nicholas Andry, the founder of orthopedic surgery, wrote in his book, "Orthopedia": "Moderate exercise is the best means of preventing or even curing disease." It will be waste of time to go into details of the value or effect of massage and exercises in cases of lack of normal motion of muscles. These facts are well known. However, it may be of interest to specify the methods used in Montefiore Hospital.

The exercises are usually of two types (passive and active). (1) Passive exercises are of two forms, either (*a*) the Swedish movements given by the masseuse or masseur after the massage. This form is very useful but rather limited, as the patient does not use his will power to do the movements himself; it is useful in cases where only a few muscles are paralyzed, as in anterior poliomyelitis or paralysis due to nerve injury. Even in these cases volitional or active movement is encouraged. "If there is a little movement," said Jean Pierre David at another occasion, "nature will soon make it a little more."

(*b*) In the second subdivision of passive exercises are the ones given by means of the elaborate machines in the Zander room. There are apparatuses for passive and active exercises and resistance machines. The principle here is, "that a single muscle has no existence in the physiology of the brain. The brain knows nothing of muscles, only of movement." (Duchenne.) By using these apparatuses, group action of muscles is called into play. The results are very good. Lately, however, it was found that the patients do the exercises unwillingly. They get tired of wiggling a machine or driving a stationary bicycle. One thus gets the patient as a passive agent and not as an active one, which is the most desirable. We are, therefore, encouraging the second type, *i.e.* active exercise, which is also of two forms. (1) Work in a curative shop, occupational therapy. The patient works in the shop making baskets, rugs, toys, etc. The work is selected to suit the desires of the patient and the nature of the disease. (2) The natural active exercises. He is taught how to stand and walk and jump and made to do that. It may be suggestive to introduce dancing in some cases. One should take away wheel chairs and crutches early and make him depend on his natural resources. (The patient should be encouraged to use his hands at the table for meals or at his card game in which he may be interested or in the needlework).

For many reasons the contraction set up in a weakened muscle by a volitional stimulus is better than that set up by a faradic or galvanic stimulus (or passive exercises), because only volitional impulses can set groups of muscles into normal action. The voluntary impulse not only plays on the muscle-controlling machinery of the spinal cord but also on another reflex mechanism—the vasomotor.

There is another form of exercise, and that is the one produced by faradic or galvanic currents. It will be a surprise to learn that the "electric" exercises are not much resorted to in this institution, though we have so many neurological cases . We believe with Duchenne, who noticed that faradization could not replace normal voluntary impulses as a means of keeping a paralyzed muscle in health and preventing it from undergoing atrophy. He came to the conclusion that it was only as voluntary control was returning that the application of faradization could help in recovery. (Keith in Menders of the Maimed.)

Though we have so many elaborate and expensive electrical apparatuses, we probably use in a whole year less electrical current than a certain orthopedic hospital in New York City uses in one day. The neurological attendings, some way or another, do not prescribe them, as they feel that those patients have been fed enough on that "humbug" before they landed here. (It is good only for psychic effect but not for real effects.) I personally never use "magic electricity." I consider it a waste of valuable time to treat with that form of exercise. It was in this institution where we used electricity a great deal in former years and, in another institution, where electricity is being used freely and I was in full charge of the electrical department for six months, that I gained the impression that it is valueless or, at least, its value has been greatly exaggerated. I have therefore abandoned it and do not use it in private practice or in acute cases under my care in another hospital (Fordham).

For spastic cases, special exercises are used, such as walking on inclined plane to train the patient to use his ankle, knee, and hip. Crossing objects of different heights teaches the patient the proper way of avoiding obstacles and to raise the feet from the floor. Carrying a heavy load in one hand makes the patient incline toward the other side, thus better balance can be retained when there is a tendency to incline to one side. Walking along a stick suspended between two chairs helps greatly to keep balance. There are many other exercises to which one can resort, in order to teach the patient coordination of the lower limbs, but the details cannot be discussed here. (Particulars will be published in another article in the near future.)

Case VII.—Philip T., aged nineteen; diagnosis, dystonia musculorum deformans. Duration of disease since eleven years of age. Entered Montefiore in January, 1919. By proper exercises he learned how to walk, even to cross glasses put in his way. Can make different toys in the occupational room.

Case VII.—Rebecca A., female, aged twenty-two; diagnosis, anterior poliomyelitis, with some functional element. Attack dates to 1916, when the epidemic of anterior poliomyelitis was raging in New York City. Patient entered Montefiore December, 1918. Examination showed left upper: partial paralysis of deltoid, pectoralis, weakness of forearm and wrist muscles. Choreic movement of left hand present. Lower extremities: right—weakness of abductors. Some spasm of the foot muscles. Spine: lateral curvature and prominent abdomen. Patient was observed during sleep and found that all the choreic movements disappear, and the spine was kept straight. Left lower extremity: all muscles paralyzed with the exception of flexors of the toes. No contractures present. Various

diagnoses were made, such an anterior poliomyelitis, dystonia, spastic monoplegia, and hysteria.

The orthopedic treatments were as follows: Patient was put on a Bradford frame and the body tied to it to correct the lateral curvature and control the choreic movements. On the feet plaster splints were applied. After six weeks the spasm in the limbs and back was relieved. She was put on her feet in July, 1919. Began to walk at the end of July, 1919. At present has a brace on the left lower extremity extending to the groin; can walk without support.

Comment.—This patient demonstrates the following facts: (1) The difficulty of making a proper diagnosis in some of the cases. (2) The necessity of strict cooperation between the neurologists and orthopedic surgeons. (3) The relaxation obtained by plaster splints on the limbs, and the Bradford frame on the spine. (4) The necessity of early walking in functional cases.

Conclusions.—1. No patient with "chronic nervous disease" should be labeled "chronic invalid" or should be pronounced such. Many patients can be improved.

2. More attention to orthopedic treatments will be of great help to patients afflicted with severe forms of neuromuscular diseases.

3. Proper cooperation is necessary between the neurologists and orthopedic surgeons.

4. Proper position of limbs to prevent contractions and deformities will help to restore normal motion.

5. Plaster splints or braces for limbs are to be applied when motion is to be encouraged.

6. Plaster splints will relieve the hypertonicity and spasms found in many types of nervous diseases.

7. Crutches and cane must be used properly if the real group action of muscles is desired.

8. Voluntary exercise is to be urged in preference to passive.

9. Massage and mechanotherapy are of great help but cannot replace volitional movements.

10. Electricity in all forms may be dispensed with. It has only a psychical value which in chronic cases cannot be of any use.

11. This class of patients requires an extraordinary amount of endurance which the family physician is not anxious to comply with. But if properly carried out, the results are sufficiently compensating and will bring the highest gratitude from the patients.

I wish to thank Dr. S. Wachsmann, the Medical Director of Montefiore Hospital, whose great interest in neurological orthopedics has afforded me ample opportunities for observation and study of these various cases. I also wish to express my gratitude to the neurological attendings at Montefiore for referring numerous cases to me.

THE TREATMENT OF EPILEPTIC MANIFESTATIONS IN CHILDREN FROM THE STANDPOINT OF THE CONSTITUTIONAL BASIS.*

BY E. BOSWORTH McCREADY, M.D., F.A.C.P.,

PITTSBURGH, PA.

FOR centuries the pathogenesis of idiopathic epilepsy has been one of the baffling problems of the medical profession, consequently therapy has been principally directed toward the suppression or mitigation of the convulsive crises, consisting for the most part in saturation with depressant drugs, which, "while reducing the number of seizures, simultaneously aggravate the morbid process."

Adequate proof of the exact nature and cause of this frequent and fearsome disease is still lacking. While in many epileptics coming to autopsy definite pathological brain tissue conditions can be demonstrated microscopically, the character of the changes differs widely as observed by different investigators, some describing a generalized gliosis, others, areas of sclerosis in different parts of the cortex, while still others have observed degenerative changes in the ganglion cells. The existence of these lesions does not prove, however, whether they are the essential cause of the epilepsy, whether they are developmental (hypoplastic) in origin, acquired, or are the result of the epilepsy. The theories of Clark as to the psychogenetic element in the convulsions are applicable to a small percentage of epileptics and of significance in the inauguration of occasional attacks in others. It is thought by many observers that the epileptic attacks are due to the accumulation of toxic wastes in the blood. Sajous strongly supports this view and contends that such accumulation is due to inherited or acquired hypoactivity of the adrenal system, particularly the anterior pituitary as test-organ. The investigations of Johnston, McKennan, Tucker, and Munson upon the sella turcica and the pituitary would seem to lend strong support to the theory which assigns to the pituitary body an important place in the etiology.

The epileptic is usually the product either of a "bad heredity" or of unfavorable gestational and environmental influences or of a combination of both. The same influences that operate in the production of constitutional inferiority (degeneracy or hypoplasia) in general are responsible for the epileptic constitution. These may be briefly summarized as:

1. Hereditary: Due to defects in the chromosomes of the germ cells of parents.

2. Environmental: Due to toxemia from various causes in parent or parents affecting the germ cell or cells, resulting in a defective impregnated germ, or to toxemia in the mother or to local disease in

*Read at the annual meeting of the American Therapeutic Society, June 3 and 4, 1921. (See page 387.)

the endometrium leading to defective or insufficient nutrition of the fetus or embryo.

3. Both hereditary and environmental forms occurring in the same individual.

Any interference with the natural forces of growth by vitiating influences modifying cell nutrition and development tends to become aggravated through the close interrelation and interdependence of the various systems of body cells, among the most important of which are those initiators and regulators of correlative growth—the ductless-glandular and vegetative-nervous systems, and further disturbance in growth and development results. The structures which were the last, phylogenetically, to develop and to achieve effective complexity, the endocrine, central nervous, and vegetative nervous systems, are most likely to suffer, even though the rest of the soma escape with little injury.

It is pretty definitely established that the endocrine system controls the metabolic processes and presides over growth and development in infancy and childhood; that upon its integrity depends mental, physical, and reproductive efficiency in adult life, and that it maintains catabolic balance during senescence. Thus it is evident that in evaluating the various factors contributory to the epileptic constitution the endocrine system must be given serious consideration. The writer has failed to find any constant and peculiar endocrine anomaly in epileptic children, nor has he found any essential difference in the endocrine abnormalities of inferior children with epilepsy and those who have never had convulsive attacks, yet varied manifestations of endocrine imbalance are common in these patients and the highly satisfactory results following treatment, in properly selected cases, by organotherapeutic measures, is in his mind significant evidence as to the implication of the endocrine system in the etiology.

As the ductless glands are themselves vegetative organs, supplied by vegetative nerves and possessing central projection fields, their functions are, in great measure, regulated by the nervous system, and in turn the excitability of the nervous system (the vegetative, particularly) is influenced by the hormones which the endocrine system gives off to the circulation. Thus we frequently find definite indications of vegetative nervous disequilibrium.

The attempts to establish the gastrointestinal system as the prime offender in epilepsy have failed of success. Most epileptics are constipated and the constipation likely has more or less influence (toxic absorption, reflex irritation, etc.) upon the severity of the disease, but it is probable that gastrointestinal anomalies are little, if any, more frequent than in other organically inferior individuals. When these anomalies do exist, however, their treatment by appropriate measures exerts a favorable influence upon the severity of the disorder.

Anemia is an almost constant manifestation of constitutional inferiority in children, particularly in those with epilepsy. The developmental arrest, whether hereditary or acquired, affects the blood-making organs and as a result there is a hemic dyscrasia, which the writer is in the habit of referring to as "hypoplastic blood," blood which is ontogenetically incomplete, resembling the fetal type. The hemoglobin is low in percentage and is unevenly distributed, the red cells are decreased in number, are irregular in shape and size, and many are nucleated; myelocytes may be present and usually there is lymphocytosis and an increase in the eosinophiles.

The epileptic child, like other constitutionally inferior children is apt to present anomalies, as visual defects, enlarged tonsils and adenoids, phimosis, impacted teeth, etc., which serve as reflex sources of irritation aggravating the convulsive tendency, sometimes even to the extent of determining the occurrence or absence of attacks; for the epileptic individual can carry without convulsions a certain load of constitutional and functional anomaly, but when the load becomes too heavy convulsions ensue. The aim of therapeusis is both to lighten the load and to increase the patient's carrying power. The affective peculiarities of the epileptic are often apparent from birth. He frets at slight bodily discomforts, or from the mere tedium of existence, is peevish, easily startled by noises, over-sensitive to impressions of all kinds, is self-willed, with extreme lability of mood. While he usually sits up, crawls, walks, and talks at about the usual time, he fails to develop the ability to perform the finer muscular adjustments, and continues to be clumsy and incoordinate. Usually he is hyperenergized, when hereditary factors predominate in the etiology, or alternately restless and lethargic, when the developmental arrest is both hereditary and environmental in origin. While epilepsy is often accompanied by a varying degree of mental enfeeblement it is sometimes difficult to determine how much of this is the result of the developmental arrest and how much is deterioration resulting from the fits. The psychic peculiarities of the epileptic personality correspond closely to the degree of developmental arrest of the nervous system and consist, chiefly, of egocentricity, supersensitiveness, and emotional poverty. It is in accentuation of these traits, and in the absence of a sense of inferiority that the epileptic personality differs from the neurotic. The varied manifestations of the instinctive defects are ably and fully treated by L. Pierce Clark in numerous articles.

The rational treatment of epilepsy consists, not so much in suppressing the convulsive manifestations as in removing and counteracting those factors and influences which are of etiological and contributory significance, and by so doing to modify the individual's constitutional reactions. We have seen that the epileptic has an endocrine system, a nervous system, a metabolic system, and a circulatory system of peculiar stamp, and this individual differs in his susceptibilities and reactions to stimuli, physical, chemical, psychic, and social, from beings of normal make-up. It is especially important that treatment be instituted in early years when developmental trends may be directed and modified.

Recourse to depressant drugs, as the bromides and luminal, should be made only after every other therapeutic aid and corrective measure has been exhausted, or when, for some good reason, it is advisable to suppress the attacks temporarily until other lines of treatment become effective. All sources of reflex irritation and foci of infection should be removed, and their removal is sometimes sufficient to arrest the convulsive attacks perma-

nently, but usually such procedure is but the preliminary to effective treatment.

It must always be kept in mind that our aim is to effect remote rather than immediate results and that we are attempting so to modify the individual's developmental trends—his cellular and chemical constitution—as to lessen his response to irritative factors which ordinarily inaugurate a convulsive reaction. The syndrome of suboxidation characteristic of the disease furnishes definite therapeutic indications. Thyroid in small doses is useful in selected cases and especially in young subjects. The dose, except when definite hypothyroidism exists, which is not unusual, should be very small and very gradually increased or the condition will be aggravated as a result of excessive metabolism. The use of pituitary substance has met with success in the hands of Tucker, McKennan, and others, and the writer has also seen excellent results follow its use, especially in children of the dystrophia-adiposis-sexualis type. He believes, however, that the endocrine implication is usually pluriglandular and, unless contraindicated, uses thyroid, pituitary, suprarenal, and thymus in combination, finding that by so doing he achieves better results than from giving a single gland substance or extract.

Stimulation of the endocrine system to correlative activity is not the only indication to be met. While the endocrine system influences the vegetative nervous system and is concerned in blood genesis, the action is reciprocal and to influence body chemistry effectively we cannot depend upon endocrine therapy alone. Many epileptics show definite symptoms of vagotonic irritability. In these belladonna or atropine is useful, given in ascending doses until the limit of tolerance is reached. It is of the greatest importance to correct the anemia which is practically always present. Several patients under the writer's observation had convulsions only when the hemoglobin fell below 65 per cent. Iron, in spite of recent investigations which serve to discount its value, is, in the writer's opinion, the remedy of greatest value in anemia. It must be given in large doses over a considerable period. Faulty lime metabolism (calcium deficiency) is a natural accompaniment and possibly an important contributory etiological factor in epilepsy. For the purpose of supplying lime to the tissues the writer uses calcium chloride, or powdered oyster shell and powdered egg shell (rich in calcium carbonate), the membrane being included in the latter because of the supposed action of the contained keratin upon metabolism and development.

While various dietary restrictions have been enthusiastically advocated the writer believes that the epileptic, like other constitutional inferiors, requires a full and well-balanced diet. The withdrawal of salt in those with chloride retention is of advantage for a time, but if long continued impairs the osmotic properties of the blood and retards metabolism. The proteins are necessary to growth, to cell development in its most inclusive sense, particularly are the animal proteins essential to proper blood genesis. While it is sometimes advisable for a time to restrict the proteins when intestinal putrefaction is a factor, to do so indefinitely produces remote effects which are deleterious to the economy. The excess of potassium salts in an exclusive vegetable diet conduces to nerve irritability. The same result, for a different reason, follows a diet deficient in vitamines.

Lack of time forbids the discussion of the hygienic and educational management of epileptic children. Their hygienic needs differ but little from those of other hypoplastic children, which are taken up at some length in other of the writer's contributions. In meeting their educational requirements the psychic reactions peculiar to the epileptic constitution must be given special consideration. It is desirable, and in some cases necessary, that the child be removed from his previous environment. The psychic element in the fits is often an important factor and can best be controlled away from parents, relatives, and friends.

The alleviation of epilepsy is not a matter of a few days or a few weeks, but requires months and even years of careful intensive treatment—medical, hygienic, and educational, and when properly carried out the results are eminently gratifying to patient, family and physician.

Conclusions.—1. The convulsive manifestations of idiopathic epilepsy are the result of a dyscrasia which itself is the result of constitutional defect or inferiority.

2. In this constitutional inferiority, the endocrine system, the nervous system, the metabolic system, and the hematopoietic system are involved.

3. Rational treatment should be directed toward the correction of existing anomalies of function and toward the stimulation of normal correlative development, consisting of intensive medical, hygienic, and educational treatment under favorable conditions of environment.

4. The plastic period of early childhood is the best time for the institution of such measures.

KEENAN BUILDING.

DISEASE AS SEEN THROUGH THERAPEUTICS.*

BY G. LEVEN, M.D.,

PARIS, FRANCE.

SECRETARY GENERAL OF THE SOCIÉTÉ DE THÉRAPEUTIQUE DE PARIS.

IN the classical works issued fifteen or twenty years ago diarrhea was mentioned among the symptoms of the prodromic period of typhoid fever. Now, on the contrary, it is admitted that constipation is more usual at that period. These contradictory opinions are readily explained by the fact that formerly every kind of gastric derangement was created by the use of purgatives, and when the gastric trouble was the first sign of typhoid fever, the diarrhea was naturally due to the purgative and not to the typhoid process. This exemplifies disease as seen through therapeutics!

A certain school has been unanimous in teaching that dilatation of the stomach comes on with typhoid fever and follows it throughout. There was a double reason for such a mistake: the diagnosis rested on a most misleading symptom: the gastric ripple. Moreover, the patients were not to be fed. As a rule, when fed during typhoid, they do not

*Read by invitation at the annual meeting of the American Therapeutic Society, June 3 and 4, 1921.

(See page 388.)

show dilatation, which was deemed formerly almost unavoidable. A. Mathieu and J. Charles Roux have shown the causal rôle of insufficient nutrition in the genesis of gastric dilatation in typhoid fever as well as in other diseases. This affords a second instance of the same disease as seen through therapeutics.

This may be emphasized by the following case: A sixty year old patient, on the twentieth day of a typical typhoid fever, established by a positive serodiagnosis, had developed coma. After she had refused to take any kind of food for the first twenty days, it was found sufficient to feed her for twelve hours on milk and coffee to make her so much better that she could recognize me (I was a very near relative of hers). I was then able to tell the attending physician that we were watching a case of illness seen through therapeutics. My colleague very frankly acknowledged that he had not sufficiently insisted on the diet question and that the coma demonstrated this fact.

We are taught that icteric patients by retention get thinner; I am experimentally certain[1] that when sufficiently fed they do not get thinner and can even grow fatter, even if the icterus persists several months. The statement that all icterics by retention must grow thinner simply means that the patient has been again looked at through therapeutics; emaciation is an artificially created symptom, in which the practitioner has neglected to consider how far anorexia and insufficient nutrition were responsible for it. This view is pregnant with lessons; for, indeed, if a patient suffering from retentive jaundice grows conspicuously thinner, while sufficiently fed, one is justified in considering the case as one of some lesion leading to cachexia, usually cancer. As it is always somewhat difficult to establish the cause of a retentive jaundice, it is important to possess an easy means of laying down, after fifteen or twenty days at most, an almost positive diagnosis, or better, of setting aside the cancer hypothesis, if the emaciation stops or if the patient grows fatter. Whenever I have used the dietetic method described, it has proved true.

In cases of pregnancy, the so-called incoercible vomiting would often cease if a diet appropriate to the dyspeptic state of pregnant women were ordered. The patient is too often left to her own dietetic whims, and her vomiting seems irrepressible. This is an example of ineffectual therapeutics.

Veronal or any other hypnotic taken after the evening meal or on retiring will often act only the next day, so the patient will feel uncomfortable during the daytime. If it had been taken half an hour before the evening meal[2] it would have brought sleep during the night and been evacuated in the morning; so the day would have run smoothly. This affords another instance of therapeutic symptomatology.

How many misdeeds has anaphylaxis been charged with in "accidents which have been ascribed to it without their having anything—or hardly anything—left of the conditions described by Richet" as Marcel Labbé[3] so excellently says; these misdeeds can be safely explained if observation is cleared of misleading agents. The following example about egg-anaphylaxis is, I think, conclusive. Some persons, called "egg-anaphylactics," can digest an egg easily if they use the small salt-cellar spoon to eat it with. Why this different tolerance? An underboiled egg when too quickly swallowed, curdles in big bits which cannot pass easily through the pylorus and determine indigestion: by using the small spoon, the person must swallow very small quantities of albumen, which break up into tiny curdles on which the gastric juice works better, enabling them to cross more comfortably the pyloric strait. Here again are symptoms seen through an alimentary mistake.

I do not, in any way, deny the existence of anaphylaxis; I only believe and have long believed—as my lectures have shown[4]—that its province has been unduly extended—an opinion which Marcel Labbé[5] equally maintains.

Let us now turn from the clinical department and enter that of experimental physiology.

When I studied, first experimentally,[6] and then radioscopically with G. Barret[7], the passing of water through the stomach, my conclusions differed from those of experimentalists of the first rank (Gley and Rondeau, von Mering and Moritz, Laborde, A. Mathieu, Hirsch) whose unquestionable statements all differed one from another.

An explanation of these divergences is easily afforded. Each experimentalist had been using different technique: the distance of the intestinal fistula to the pylorus was not the same in all these experiments; and that was the only reason why the results differed. Each physiologist's observations were correct, excepting in one feature which I tried to avoid by using another method, namely, avoiding all operation upon the animal and studying the passage of liquids with the aid of the screen.

I only mention these results because they afford an instance of physiology seen through experimentation, and because it might prove useful to compare it with a case of disease seen through therapeutics.

We find in medicine as well as in physiology and therapeutics differences of opinion which are puzzling and discouraging for the physician, and which little by little bring him to believe in nothing. When he begins studying he is taught certain things; later he is told that what was true twenty years ago is no longer true to-day. It is probable that medical opinions would not change so frequently if clinical experimentalists were more accurate in ascertaining the actual circumstances of their experiments. One must acknowledge that this is a more difficult task for a physician than for a physicist or chemist, as biological phenomena, both physiological and pathological, are, and always will be, extremely complex.

However, when the experimentalist tries to go further in the investigation of the symptoms; when he is careful in determining the circumstances of his experiment; when, first of all, he avoids creating symptoms which he will afterwards falsely ascribe to the disease; when he does not study the latter through the deformation occasioned by therapeutics; when he does everything he can to be a good medical experimentalist, he will have a justified claim on both practitioners' and patients' gratitude; and sceptics will no longer be able to say: take this medicine while it still cures! Well studied,

well experimented, the medicine that has cured once should always cure.

THE ETIOLOGY OF HYPERTENSION.*

By J. F. YARBROUGH, M.D

COLUMBIA, ALA.

In speaking of hypertension we refer to the permanent type; the transient, or emotional form will not be considered. In the treatment of pellagra during the years 1912 and 1913 we discovered that hypertension, Brights disease, and certain types of rheumatism made wonderful improvement under the dietary and medicinal measures employed in the treatment of that disease. The author stated in a paper written at that time that the improvement in these conditions was so striking that he believed he was dealing with a carbohydrate diathesis. (The carbohydrate referred to is that contained in sweets and starches, not that contained in fruits and vegetables.)

Subsequent observations have vastly strengthened that belief. It would be interesting to take up separately the above diseases and study their relations to the carbohydrates; however, the time allowed, and the scope of this paper, forbid a detailed study of this phase of the subject. Therefore, our study will be confined to hypertension, or rather, the etiology of hypertension, the keystone to the arch of this medley of conditions.

Hypertension is the most anomalous and perplexing symptom now engaging the minds of the profession.

A state of chaos exists as to its etiology; this is clearly proven by the great divergence of opinion among investigators. Jacobi and his followers believe that all hypertension has its origin in nephritis. Jacobi goes so far as to state that all systolic pressure approaching 200 is proof positive of nephritis. The other school believes the etiology is to be found in the blood tree. Hemenway differs from these schools in that he believes a viscosity of the blood is the leading factor. The opinions of all these gentlemen seem plausible, as expounded by them; however, after much investigation and experience, I am convinced they are in error.

The true etiology, in my opinion, will be found in a carbohydrate acidemia. The following facts seem to be strong proof of the correctness of this conclusion:

*Read before the Alabama Medical Association held in Montgomery, Ala., April 20,1921.

1. The history of every case with which I have had to deal showed a large preponderance of carbohydrates in the diet.

2. They all showed an acidemia.

3. In former years a large percentage of our nephritis cases was addicted to the use of alcohol (a pure carbohydrate product).

4. In every instance the pressure has quickly fallen to normal under a strictly protein diet, and such drugs as would promote alkaline secretion, or the administration of an alkali.

5. In every experiment made, a substitution of the proteins by the carbohydrates, and the withdrawal of the alkaline promoting drugs, was quickly followed by a rising tension.

A careful study of the part played by the carbohydrates in the process of digestion also offers strong proof of the above hypothesis. It is known by all chemists that the end- or by-products of carbohydrate digestion are acids, too various in kind and number to be discussed in this paper.

The main function of the liver is to neutralize these acids and other poisonous products. A long preponderance of the carbohydrates in the diet produces these acids in sufficient quantity to cripple the secreting power of the liver; a natural consequence of this crippled function is a blood stream filled with these acids. The detailed treatment of this condition is not contemplated in this paper; however, I feel constrained to say here that in advanced cases, the fate of the patient absolutely depends upon the restoration of the hepatic function.

Acids are astringents, therefore contract tissues; what then would be more natural than a contraction of the arterioles by a blood stream filled with this poison? The lumen of these vessels would naturally be materially restricted. Mechanical engineering teaches that it requires more power to deliver a given amount of water in a specified time through an inch pipe than through a two-inch pipe.

The same principle is here involved; nature demands that a certain amount of blood be supplied to the parts in a given time, if from any cause the lumen of these vessels become lessened, it naturally follows that more power is required to maintain a proper circulation. What then could be more natural than an increased blood pressure under such conditions?

In further support of this etiology, we quote Monakow as he was quoted in a recent number of the MEDICAL RECORD of New York: "Monakow presents evidence that permanently high blood pressure is always preceded by abnormal contraction of the arterioles in extensive vascular regions. These contractions of the vessels can be induced by nervous influences (disturbances in the domain of the sympathetic, from emotional influences), or they may be induced by changes in the internal secretions, or by poisons. A high blood pressure is thus a symptom which—like fever—has no single etiology. To attempt to trace this symptom to a single cause—disease of the kidneys—is futile. Even with the so-called nephrosclerosis, the rise in blood pressure is not conditioned by the kidneys; the kidneys may be entirely intact not only functionally, but anatomically. The trouble is a primary hypertonia which may be of different origins."

Dr. Beaumont S. Cornell, in the *Journal of the American Medical Association*, March 12, 1921, offers the following corroborative evidence: "Elsewhere I have emphasized the clinical evidence of acidemia in early cases of chronic nephritis. It was shown in ninety-five cases out of a hundred in which nephritis had been present under three years there was a certain kind of dyspnea that seemed unexplained by the heart. In the present article, I will give further observations. It is remarkable how, after, say four doses (20 grains each) of the alkaline salt (sodium bicarbonate) most extreme dyspnea of this type subsides, and usually disappears altogether. There is then no dyspnea of any kind left, thus proving that the heart had no part in causing the respiratory distress."

The writer in a former article gave the following explanation of the dyspnea described by Dr. Cornell: "An acid blood cannot absorb oxygen, hence dyspnea naturally follows an improper oxidation of that fluid. The bicarbonate of soda quickly alkalinizes the blood, oxygen is immediately absorbed, and the disappearance of the dyspnea is the logical result." In late years we have had much discussion as to the initial lesion of hypertension in cardiovascular renal disease; the heart and kidneys have both had ardent advocates. It would seem from the above study that the real lesion was in neither of these organs, but had its inception in a carbohydrate acidemia (with accompanying hypertension) long before any symptom of cardiovascular renal disease made its appearance.

With this heterogenous mass of poisons filling the blood stream for months and years, would it not be strange if the vessels containing them and the sewer through which most of them pass out of the system did not become seriously affected? A natural consequence, therefore, of this condition would be cardiovascular renal disease.

In closing, the history, diet, treatment, and results obtained in the three principal types of hypertension will, I believe, add value to this paper.

CASE I—*Simple Hypertension:* Mrs. A. D. C., white, age 65, housewife, admitted Nov. 2, 1920. (A note from her physician stated that her blood pressure had averaged 230 for the past two years, and that he had never been able to find albumin in the urine.) Blood pressure 240. Skin dark brown; constipation, indigestion, oral membranes, tongue and throat scarlet; proctitis, vaginitis, with excoriating acid discharge; much distress from gas after meals. No appetite. Diet had consisted for the past several years of cereals, potatoes and rice. She was passing only 8 ounces of urine in 24 hours, no albumin, no cardiac lesion. A nervous and mental wreck.

Treatment: Thirty drops dilute nitric acid in glass of water one hour before meals. An ounce or two of phosphate of soda when a purgative was necessary. Fifteen grains trional at bedtime.

Diet: Two raw eggs, four ounces pure cream, the juice of two oranges and a pint of sweet milk three times a day. All the water she could be induced to drink.

Results: Within eight days her pressure had fallen to 140. The urinary secretion had increased to 40 ounces. We now added to the diet chickens, fish, beef, peas, and beans, bean bread and all fruits and vegetables except beets and bananas. She left the hospital January 15, 1921, greatly improved; nervous and mental condition practically normal; pressure 140, eating and sleeping well, normal stool every morning, weight 88.

CASE II.—*Interstitial Nephritis:* Mr. T. C. McC., admitted Feb. 15, 1921. White, age 61. Capitalist. This patient had had high blood pressure and albumin for more than ten years. In New Orleans his case had been diagnosed "Brights" and a bad prognosis given. Later in New York the same diagnosis and prognosis were made. He entered the hospital Jan. 15, 1921, in the following condition: Blood pressure 245, urine loaded with albumin, skin dark brown, constipation with hard white stools. Exceedingly nervous, insomnia, vision greatly impaired, indigestion. Oral cavity, tongue and throat scarlet. Was voiding 14 ounces urine in 24 hours. Diet had consisted largely of rice and sweets for several years.

Treatment: Thirty drops dilute nitric acid in a glass of water one hour before meals. One or two ounces of phosphate of soda when a purgative was necessary. Was induced to drink all water possible. Fifteen grains trional at bedtime.

Diet: Two raw eggs, the juice of two or three oranges, and a quart of sweet milk three times a day.

Results: At the end of the first week his general condition had improved; urine had increased to 50 ounces. Stools were still hard and white. The acid was discontinued and 8 grains ox-gall was given in its place. In less than a week the stools were soft and dark; the gall was now displaced by the acid. The blood pressure had fallen to 175. There were now added to his diet peas, beans, bean bread, chickens, beef, fish, and game, and all fruits and vegetables except beets and bananas.

At the end of the fifth week his condition was as follows: Blood pressure 130, no albumin, skin clear, appetite good, sleeping well, normal stool every morning, vision practically restored. On a visit to the hospital a week ago his pressure was 138, no albumin.

CASE III—*Parenchymatous Nephritis:* Mrs. J. D., White, age 40, housewife, admitted to hospital in December, 1914. General anasarca with the peculiar pallor of chronic parenchymatous nephritis. Ears, nose, lips, and fingers cyanosed. The edema and dyspnea were very distressing symptoms. Constipation; urine loaded with albumin. Systolic pressure 100. She was voiding 12 ounces of urine in 24 hours. She had recently been given almost every known drug that was supposed to increase urinary flow without result. For several years her diet had consisted largely of corn bread, syrup and potatoes.

Treatment: Thirty drops dilute nitric acid in a glass of water one hour before meals; large quantities of phosphate of soda with the hope of reducing the edema.

Diet: Two raw eggs, the juice of two or three oranges, and all the sweet milk she could be induced to drink. No salt; practically no water.

Results: In one week the edema and dyspnea had disappeared; the urinary flow had increased to 60 ounces. The patient slept prone on the bed without discomfort. She was now given chicken, beef, fish, peas, beans, bean bread, all fruits and vegetables except beets and bananas.

At the end of the sixth week she was dismissed practically recovered; blood pressure had risen to 140. This woman has had no return of the nephritis and is now in good health.

In the initial stage of this type of nephritis, we have high blood pressure—it falls after the cardiac muscle has become weakened. We occasionally find low pressure in the interstitial type from the same cause.

These case histories give only the leading features of the treatment; many details have of necessity been omitted because of a lack of space.

Passage of Virus of Epidemic Encephalitis from Mother to Fetus.—Levaditi and two others have shown this transmission experimentally. A gravid rabbit inoculated with the virus in question died on the 11th day. Experiments with the brain of the mother and one of the young, in the course of which healthy rabbits were inoculated in the usual manner, showed that the virus had gained access to the cerebrum of the newborn rabbit through the placenta, with the possibility of transmission through the milk.—*Gazette des Hôpitaux.*

ACUTE ANTERIOR POLIOMYELITIS OF UNUSUAL TYPE.*

WITH REPORT OF A CASE.

By LOUIS HANNAH, M.D.,

SYLVANIA, GA.

THE presentation of this type of poliomyelitis is of diagnostic interest chiefly. Recognition of the disease is complicated by manifestations of intracranial involvement, which, until the type of paralysis is determined, leads one to suspect some organic alteration in the brain or its blood supply as the primary cause of the symptom syndrome. It is true that we encounter but rarely tumor formations, apoplexy, thrombosis, inflammation, or even syphilis, of the brain in very young children; but such exceptions are possibilities, and, clinically, the case under consideration is one of the exceptions.

Since many features of resemblance between encephalitis and poliomyelitis have long since been established, we have been confronted with the question as to whether the two maladies may not represent simply different manifestations of a single disease entity, with a common etiology. As late as 1914, it was stated with certainty by McKee and Wells in their text book, "Practical Pediatrics," that "infantile spinal paralysis and polioencephalitis represent but different phases of one and the same disease." Furthermore, to quote the same authors, "In addition to such cases—the well recognized types—every epidemic of size contributes its cases of polioencephalitis with resulting spastic hemiplegia, the superior and inferior types of Wernicke, facial paralysis, bulbar palsy, paralysis of the neck muscles, and paralysis of various muscles of the trunk. Again, though rarely, cases of the Landry ascending type of paralysis occur." Should we accept the question of this theory in the affirmative, then the case to be later described might be regarded as of the borderline type. However, recent immunologic investigation at the Rockefeller Institute seems to determine the question more nearly, and with more obvious and convincing evidence, in favor of an individuality rather than an identity of poliomyelitis and encephalitis.

Concerning the etiology of sporadic poliomyelitis, it has not been determined whether or not its causative agent is identical with the virus of the epidemic form. However, from an immunologic standpoint, Amoss, in a report published January 8, 1921, stated that the serum employed in epidemic poliomyelitis was "scarcely adapted" to the treatment of the sporadic types. In the present instance, no definite source of infection could be ascertained, as there were no other occurrences of the disease in the community. In the absence of fever or other evidence of an infectious process, Starr suggests that the cause of these unusual forms of the affection may be a primary degeneration of the ganglion cells, or may be a hemorrhage or thrombosis of a spinal vessel. The same author regards the two types of onset (with and without fever) as quite distinct, and considers their pathological basis as probably different. The same sex, age of maximum liability, and seasonal incidences obtain in the sporadic disease as in the epidemic form.

*Read before the Screven County (Ga.) Medical Society, May 12, 1921.

CASE REPORT.—R. W., a boy 6 years old, son of a farmer living eight miles from the city, was seen in consultation with Dr. W. R. Lovett on May 4, and again on May 6 and on May 11.

The patient's family history is negative, excepting that one brother, 8 years old, now has slight "weakness" of one side of the body, including the limbs, with which he has been affected since birth. The past history is entirely negative, including exanthemata and trauma.

Present History.—When first seen, the patient exhibited left partial hemiplegia which had appeared suddenly, three days before, to mar an apparently perfect record of health. The paralysis was flaccid, and there was also present at this time right internal strabismus, symptoms of optic neuritis, impaired vision, and slight temporary hemianopsia. There was no inequality of pupils, which also reacted normally to light. The deep reflexes were normal, as was also tactile sensation. There was slight motor paralysis of the tongue on the right side. Malaise and apathy were also noted, although the child displayed an unusually bright mentality, as evinced by his ability to recite readily the alphabet in reverse order of its letters. The only incident which might be considered prodromal occurred three days previous to the attack, when the patient complained of slight abdominal colic.

Later observations disclosed progressive disability, and while for the first few days he had been able to walk with little or no assistance, he was now confined to bed and was practically helpless. At this time there were signs of slight motor aphasia and dysphagia, temporary retention of urine, abolition of the left patellar, wrist, ankle, and plantar reflexes, with the presence of marked Kernig's sign (due to contracture) and of very slight Babinski reflex on the paralyzed side. The right patellar reflex was also abolished and the right Kernig negative. He had had several marked sweating spells and attacks of vomiting, and suffered some exhaustion. The affected limbs were cold but showed no edema. The upper limb paralysis was of the lower arm type and presented much greater disability than did the leg; and while the patient could raise the arm to his head, there was total loss of control of his forearm. There was no mental impairment, and no headaches, fever, loss of consciousness, convulsions, tremor, nor chills at any time during the course of the attack. The patient never complained of any pain whatsoever, and only during the first few days was there tenderness over the spine. The only variations in his general condition were a slightly accelerated pulse, temporary anorexia, coated tongue, and constipation. There was never bladder nor rectal incontinence. Tests were not made for reactions of degeneration, and at the present time atrophy is not discernible.

The general physical examination of the patient proved negative, excepting the effects of paralysis. The Moro test for tuberculosis was negative. The blood pressure was 85, and hemoglobin 70 per cent.

Examination of blood showed: Leucocytes 7,600; blood picture negative; malaria negative; Widal test negative; Wassermann negative. The spinal fluid macroscopically was normal; spinal fluid pressure increased; albumin slightly increased, with a trace of sugar, or other reducing substance, present; no cells were found other than a few erythrocytes, seen microscopically and probably due to the needle puncture; the reaction was faintly alkaline; the Wassermann reaction was negative. The urine showed: specific gravity 1,017, acid reaction, no albumin nor sugar, and was negative microscopically. We were unable to obtain a specimen of feces.

With reference to treatment of this case the writer is not prepared to present any conclusions, as the patient was seen only in consultation, and the general management was left to the family physician. The measures decided upon were hydro-, electro-, and mechanotherapy, with massage, and the administration of urotropin, strychnine, laxatives, and general alteratives. There is no specific remedy known for this type of poliomyelitis, and the serum used in the epidemic form has not proven applicable to sporadic cases.

Comment.—The features of interest in connec-

tion with this case were the total absence of fever, headache, pain, and convulsions, and the presence of a hemiplegic type of paralysis, with facial involvement. As to the infrequency of afebrile infantile paralysis, Starr has concluded that only 25 per cent. are of this character; and statistics show a smaller incidence of paralysis affecting the eyes, tongue, and face, as a result of invasion of cranial nerve nuclei by this disease, than occurs in the epidemic form. However, the most striking variation from the usual manifestations of sporadic poliomyelitis is the incidence of hemiplegia, as indicated by the fact that of 1292 cases of this disease reported by five observers, from 1864 to 1908, only 63 cases, or less than 5 per cent., were of hemiplegic type.

FOREIGN BODIES IN THE EXTERNAL AUDITORY CANAL.

WITH TWO CASE REPORTS.

BY JOSEPH FRIEDMAN, M.D.,

NEW YORK.

INSTRUCTOR, NOSE AND THROAT DEPARTMENT, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSOCIATE OTOLARYNGOLOGIST, BETH MOSES, WILLIAMSBURG AND CONEY ISLAND HOSPITALS,

AND

SAMUEL D. GREENFIELD, M.D.,

NEW YORK.

ASSISTANT ATTENDING OTOLARYNGOLOGIST, WILLIAMSBURG AND CONEY ISLAND HOSPITALS; ASSISTANT ATTENDING OPHTHALMOLOGIST, BETH MOSES HOSPITAL; CLINICAL ASSISTANT, NOSE AND THROAT DEPARTMENT, MANHATTAN EYE, EAR, NOSE AND THROAT HOSPITAL.

FOREIGN bodies in the external auditory canal oftentimes offer difficulties of such a nature that the ingenuity of the otologist is taxed to the utmost. Very frequently these difficulties are augmented as a result of the injudicious and unwise attempts at removal in unskilled hands. What would ordinarily be a simple and safe procedure is indeed rendered a more or less hazardous task by the overanxious physician in his hurried and unsuccessful manipulations. Most of the cases in our experience that have required more than the ordinary methods of removal have been those that had previously been tampered with and particularly have we in mind the faulty and overindulgent instrumentation. That this overindulgence can be carried to an almost unmerciful state will be exemplified subsequently.

The foreign bodies that find their way into the external auditory canal are numerous and of great variety. Almost every conceivable object of a size small enough to permit of its entrance into the external auditory canal may find lodgment there either accidentally or intentionally. The wilful insertion of foreign bodies into the canal is not only a most pernicious habit prevalent among children, but we also find adults who partake of this practice. Shoe and collar buttons, glass beads, kernels, seeds, pieces of chalk, pebbles, beans and peas, pieces of match-stick and pencil lead, shot, cotton plugs, and various insects such as flies and bugs are some of the articles encountered.

The presence of a foreign body in the canal *per se*, is not of very great consequence, providing of course it is not of such size as to exert undue pressure upon the walls of the canal with its subsequent irritation or, by reason of its size and location, to cause interference with audition. A foreign body not too large to obstruct the lumen completely may remain in the canal for an indefinite length of time without producing any injury to the ear or inconvenience to the patient. As a matter of fact the patient may not be conscious of its presence, and cases have been reported in which foreign bodies introduced in childhood were accidentally discovered in adult life. Politzer reports a case in which he removed a piece of pencil lead that had remained in the ear for fifty years. There is greater danger to be feared in those cases in which interference has been instituted. The forceful and injudicious attempts at removal have oftentimes resulted in fracture of the walls of the meatus with subsequent serious involvement of neighboring structures. Not alone has the foreign body been driven against the drum, with laceration of the canal walls and destruction of the drum membrane, but with persistence it has been driven through the drum into the middle ear where it becomes impacted and in this location renders removal through the canal almost impossible. Not alone has the ear been frequently rendered functionless, but even death of the patient has been known to ensue. No one is justified in jeopardizing the usefulness of the organ of hearing or endangering the patient's life because of lack of knowledge and familiarity with the conformation of the external auditory canal and the location and slope of the drum membrane, associated with inexperience and the employment of unsatisfactory and improper instruments. We cannot impress too strongly upon the general practitioner the necessity of refraining from introducing various instruments into the ear especially when the foreign body with ordinary examination is hidden from view. Groping about blindly in a narrow irregular canal can never accomplish anything but harm to the patient, which only too often becomes of a most irreparable nature.

We wish it to be remembered that a history of the introduction of a foreign body into the auditory canal of a child is no criterion that a foreign body is present. Not until we have obtained a satisfactory view of the object can we be assured that the patient's statement is correct. One can readily see therefore that, especially in the latter case, damage is apt to result from faulty instrumentation. A curette or a hook is oftentimes introduced into the canal until it meets an obstruction and then the operator tries to engage what he believes is the foreign body. In his eagerness to extract the object, usually in a struggling child, he lacerates the drum, mutilates the canal walls, or dislodges the ossicles and with the appearance of a sanguineous discharge from the ear, he withdraws from the procedure and is then willing to transfer the responsibility. Much can be accomplished and a great deal of unnecessary traumatism and pain can be spared these patients if certain facts are borne in mind, and if those factors which govern the selection of the procedure to be employed are assiduously and intelligently considered.

The external auditory canal is a narrow irregular tube about 1½ inches in length. At its inner extremity is situated the membrana tympani, a knowledge of the exact position of which is essen-

tial if one is to perform with safety any manipulations in these cases. It should be borne in mind that the direction of the drum membrane is obliquely forward and downward and that in children this inclination is much greater than in adults. Because of this position the posterior portion of the drum is situated 5 to 6 mm. nearer the meatus than is the anterior portion. This being the case, therefore, instruments must, if passed along the posterior and superior walls, be introduced with great caution in order to avoid injury to the drum membrane; it is much safer to introduce them along the anterior and inferior walls in our endeavor to engage the foreign body.

The canal as a whole presents great variations in different individuals; in some cases being wide and straight while in others it is narrow and presents curves requiring quite a bit of difficulty and maneuvering before one is able to obtain a satisfactory view of the interior of all the canal walls. This difficulty is obviated to a great extent by the presence of the fissures of Santorini, located in the cartilaginous portion, which run at right angles to the long axis of the canal. These fissures permit the straightening of the meatus and also follow a certain amount of displacement of the cartilage during examination and operative procedures. Hence traction on the auricle in the proper direction aids materially in making a satisfactory inspection. The narrowest part of the canal is located at the isthmus, which is the point of junction of the cartilaginous and osseous portions. This is the place where foreign bodies become wedged and where if they penetrate more deeply beyond this point, the greatest obstacle is offered to their extraction. As a rule foreign bodies are driven beyond the isthmus as a result of instrumental interference; the usual location in the cases that have not been treated being external to the point of constriction.

Given a case in which we have obtained a history, either from the child itself or from the parents, that a foreign body has been accidentally introduced into the ear, what steps are we to follow in the process of its extraction? To begin with, we must have at our disposal adequate light, a head mirror, a speculum, and the proper assistance necessary to hold the child quiet so that we can obtain a good view of the foreign body. When the proper assistance cannot be had, light anesthesia may be employed to great advantage. That we must verify the statement of the patient or of its parents is of great importance, a matter to which we have previously called attention. Under no circumstances should we attempt interference unless we have ascertained to our own satisfaction that a foreign body is present in the canal. Some of us may advance the proposition that all this precaution is unnecessary; that without seeing the foreign body, the ear syringe may be employed promiscuously without any ill effects to the patient. In some instances this hit and miss affair may drive a foreign body deeper into the canal and what would ordinarily be a simple case to handle becomes a difficult one. This is especially true in those instances in which the foreign body is impacted in the canal occluding the entire lumen. Because of this latter fact the stream of water from our syringe, which is only effectual when we succeed in establishing a return flow behind the foreign body, cannot be applied here to advantage, and consequently all that it serves to do is drive the object deeper into the canal and increase the impaction. After what has been said, we believe it is obvious to all that instrumentation should certainly be precluded under similar circumstances. How much more liable is the operator to force the foreign body beyond the isthmus in these instances.

Having determined to our satisfaction that a foreign body is present, what factors concerning our case must be taken into consideration before we institute treatment?

The method of extraction of a foreign body depends upon its location in the canal, its size, whether small or large (the importance of the latter being the absence or the presence of impaction), its consistency (whether soft so that an instrument can be forced into the object itself and so engaged, or whether an instrument can with safety be introduced between it and the canal wall), and lastly upon the condition of the meatus at the time of examination, viz., whether previous attempts have already been made at removal as evidenced by impaction, inflammation, and narrowing of the canal. The majority of cases, unfortunately, that come to the specialist have already been interfered with.

In cases in which the foreign body is not impacted and in which there has been no previous interference, whether it be internal or external to the isthmus, the employment of the ear syringe, preferably one holding at least six ounces, using plenty of lukewarm water and force, and above all patience, will usually be successful in dislodging it. In the majority of cases this is all that is necessary. However, if perchance this should fail, we can very easily engage the foreign body by passing a small probe, hook, curette, or spoon beyond the object and then making pressure against it as we withdraw our instrument we can remove it. These measures, carried out carefully, should result in no injury to the lining of the canal or to the drum membrane.

In those cases in which the foreign body is impacted, but in which the previous interference has not caused reaction sufficient to render a good view of the object and its location impossible, we must determine whether the impaction is complete or incomplete, viz., whether at one or more points in the circumference of the foreign body there is no contact with the canal wall. If the impaction is incomplete, we may hope for a return flow behind the foreign body, and hence, the syringe should first be tried. If unsuccessful, we may attempt dislodgment by means of a narrow probe or hook inserted at the point where the impaction is incomplete, always exerting pressure against the foreign body and so try if possible to loosen the impaction. This should then be followed with the syringe. In the majority of cases that fall into this category, the procedure outlined will usually be effectual. If the impaction is complete and the foreign body is external to the isthmus a number of procedures may be tried depending upon the circumstances. If the foreign body is of such a consistency that it can be perforated, or if the mass can be entered, we can oftentimes loosen it so as to render a complete impaction incomplete and then further steps may be employed as above described. Occasionally, especially in the case of kernels, peas, beans,

or wood, the mass can be shrunken to allow of manipulation by the repeated instillation of alcohol. However, should the foreign body be impossible to enter and if tightly impacted deeply in the canal, then the more radical operative measures, as will be described later, must be undertaken, especially if complications arise.

A very important governing factor, which at times calls for delay in instituting any treatment whatsoever excepting the expectant plan, is the presence of severe inflammatory reaction. In these cases cold applications to the canal must be employed until the inflammation and swelling have subsided and we can learn the exact state of affairs inside the canal. Whether we are justified in waiting will depend of course to a great extent upon the presence or absence of more severe symptoms. Delay should not be resorted to in the presence of increased temperature, severe pain, labyrinth, or brain symptoms. In these cases if the simpler methods have proven fruitless then the auricle and posterior wall of the cartilaginous section must be detached and the foreign body removed. It may be necessary, although rarely, to chisel away the osseous meatus in order to reach the foreign body. In all these cases, therefore, the treatment is determined by correct judgment of the circumstances, and here, more than elsewhere, the acuteness of the physician is the leading factor in the success of the operation.

There are two cases we wish to report in detail. Both of them demonstrate very clearly those points we have tried to emphasize in regard to the damage that can result from the injudicious attempt at removal. There is no question in our minds that the complications which followed in both cases could have been avoided if the cases had fallen into the proper hands at the outset.

CASE I.—The first case was that of a little boy aged five, who had introduced a small pebble into his ear. The mother immediately took the child to a physician, who attempted to remove the foreign body, but having failed and who, according to the mother, had caused the child considerable pain, prescribed drops to be instilled. The child was not relieved and was taken to another physician, who repeated the same procedure. He likewise failed. That evening the child was seen by Dr. S. Robbinowitz, who referred the patient to us. After carefully wiping out the canal of blood, examination disclosed the following: A canal badly lacerated, the foreign body impacted deeply in the canal, extending probably beyond the annulus tympanicus into the middle ear, a drum membrane bady lacerated with the malleus handle projecting into the canal. Several attempts at removal with a small hook failed, difficulty being encountered in trying to pass the instrument between the mass and the canal wall. In view of what had gone before with an already well-established traumatic otitis and the child suffering with pain and temperature, we decided to remove the pebble through the posterior route. The child was admitted to the Bikur Cholim Hospital the next morning and under anesthesia an incision was made close to the postauricular fold. The soft parts were retracted, the cartilaginous canal exposed, detached and opened and the foreign body grasped and removed. The child left the hospital several days later and came to the office for subsequent treatment. The otitis ran a most protracted course. The mastoid never seemed involved, but due to the extensive destruction of the drum membrane more than three months elapsed before the middle ear became dry.

CASE II.—The second case was less fortunate. A little boy aged four and one-half permitted an older brother to introduce a shoe button into his ear. Nothing was said of the accident until three days later, when the youngster began to experience pain in his ear. He was taken to his family physician, who decided to undertake its removal. As commonly occurs, the physician introduced a pair of forceps and began to feel for the foreign body. Not succeeding, his attemps became more violent and very soon the youngster began to object, and the mêlee ended with the child bleeding profusely from the ear. The child was sent home and told to return the next morning. During the remainder of the day the youngster was very uncomfortable and complained bitterly of earache, and consequently that evening the child was brought to our office. Examination revealed the button deeply wedged in the canal, but very fortunately the loop of the button was directed externally. It was impossible to control the vigorous youngster and we had to resort to anesthesia. It took a short time to insert a hook and thread the loop and the foreign body was quickly removed. The drum was very much congested and bulging. We incised at the same time and obtained pus. The child was put on irrigation, but apparently the otitis ran the usual course that one expects when traumatism plays a part in the etiology. For two weeks the discharge was profuse; the child was restless at night, his temperature ranging from 99° to 103°, and about this time the posterosuperior canal wall began to droop, and because of these findings, with acute mastoid tenderness, we advised operation. The child was admitted to the Williamsburg Hospital and operated upon the same day. The interesting feature of the operation was the finding of a very diseased and necrotic pneumatic mastoid. We cleaned out all the cells very carefully and completely and closed the usual way. In less than five weeks the posterior wound was healed and the middle ear was dry.

There is no doubt in our minds that both of these otitides were traumatic in origin and that the latter case developed a masteid in consequence. It must therefore be clear to all that we cannot afford to minimize the danger attendant upon the rash and hasty removal of foreign bodies from the external auditory canal in inexperienced and unskilled hands.

691 LAFAYETTE AVENUE

THE TREATMENT OF PULMONARY TUBERCULOSIS WITH SULPHUR DIOXIDE.

BY F. TWEDDELL, M.D.,

GREAT NECK, N. Y.

MORE than two and a half years ago I read my first paper[1] on the use of sulphur dioxide inhalations in the treatment of pulmonary tuberculosis. This was an experiment then and will remain one for some time to come until I shall have had better facilities for carrying out this treatment in some institution on a larger scale. My experience has shown that practically all men exposed to inhalations of sulphur dioxide are immune to tuberculosis. This immunity arises from no other known cause. Consequently I feel justified in continuing experiments along these lines.

I know of several men who are using this gas with success, and I have heard of others who have not had success with it. It must be borne in mind that this treatment is unquestionably in the experimental stage. Nonsuccess is due to several causes: (1) Unsuitable cases, *i.e.* long-standing chronic cases and those in too far advanced stages. (2) Fibroid phthisis, which I have shown[2] does not respond to the treatment. (3) Using the gas too strong, or too often, or prolonging the time for inhalations. (4) Using impure gas. Only the pure

gas as supplied by the King Chemical Company, made from powdered sulphur, should be used. This gas is liquefied under pressure and sold in tanks. A pound will last a month. The gas should pass through a rubber tube into a test tube half filled with water, so as to purify it again. The water in the test tube should not be changed, as one volume of water absorbs forty volumes of the gas before it enters the room. When the water gets low in the test tube more can be added to it.

Sulphur dioxide made from burning powdered sulphur or sulphur candles is very irritating and impure, and the amount of the gas cannot be controlled. Also sulphur dioxide made from pyrites is impure and irritating. None of these gases should be used.

Marked improvement is noted within a day or two after beginning treatment. Before treatment the patient has been coaxed to take a little milk or an egg or orange juice. He does not sleep well, is awake most of the night and coughs day and night. Within 48 hours he eats everything in sight and sleeps all night without waking. His cough becomes loose and he brings up enormous amounts of mucus with gray lumps in it. In about two weeks' time he hardly coughs at all except for a few minutes when he gets up in the morning. He then gets rid of the mucus which has accumulated during his sleep. The sputum has changed, there are no more gray lumps, it is white and frothy and greatly diminished in amount. About this time it will be noticed that the temperature and pulse are coming down and that the weight is going up.

As a rule patients use the gas far too strong. Improvement is so rapid and so steady that patients are led to believe that the stronger the gas the quicker the recovery. This is a mistake and should be guarded against. The gas in the room is strong enough when it can be noticed by the odor or the taste. When this is the case it should be turned off almost entirely, allowing about 50 or 60 bubbles to the minute to replace the gas which is lost by coming in contact with moisture, or by escaping from the room through cracks in the windows and doors. When used too strong or for too long a time, the patient will notice a warm, burning sensation below the sternum and in the epigastrium, or he will cough incessantly. In this event he must leave the room at once, or turn off the gas and open the doors and windows, and not take another inhalation for at least three hours. Some patients, after an inhalation, get a fit of coughing when they go out in the open air. When this happens they are advised to stay indoors for 15 or 20 minutes before venturing out of doors.

Tuberculous patients look forward to and enjoy the inhalations, and, as a rule, never cough during the treatment, whereas persons with sound lungs may cough a great deal. Usually three inhalations a day are sufficient, one early in the morning on rising, one in the middle of the day before the midday meal, and one late in the evening. In this way the interval at night will be shortened as much as possible. Later, after marked improvement, the midday inhalation can be left out. Patients at all times must refrain from much talking, which always subjects the lungs to a strain.

I do not advise inhalations in cases suffering from an active pleurisy, unless great care is taken. Deep inspirations aggravate it and complicate matters. The patient should either wait until all active signs of the pleurisy have disappeared and then begin treatment, or go to the inhalation room without, however, at any time attempting to expand his lungs, but just breathing normally. This is, of course, a disadvantage as the gas cannot reach the apices without deep inspirations.

I wish to report some very interesting and unusual experiences. I was called in consultation to see a patient, 74 years old, with involvement of the left apex, rales above and below the clavicle in front, and in the alarm zone behind. No bronchial voice or breathing anywhere. Sputum reported positive by two separate laboratories. His physician had already put him on sulphur dioxide inhalations a few days before. Eighteen days later I saw him again, the rales had completely disappeared, but there was cavernous voice and breathing in a small area, the size of a 25-cent piece at the outer side of the first interspace! A consolidation must have been there before treatment, but could not be made out.

On two other occasions I noticed another curious phenomenon. Both were in the right alarm zone, and occurred in like manner. There were crepitant rales in this area, especially after coughing. After three weeks' inhalations with sulphur dioxide, bronchial breathing was noticed on *expiration only*, and ten days later there was cavernous breathing during both inspiration and expiration. Undoubtedly this was a cavity. I am unable to find an explanation why bronchial breathing appeared first only during expiration. In future when this sign appears I shall feel inclined to infer that a cavity will show up sooner or later.

A few days ago I went to the Boston session of the American Medical Association to hear Dr. Pierson's paper,[3] which obviously would be of interest to me. I met Dr. Pierson before the opening of the meeting and he asked me to discuss his paper. Although I sent in my slip notifying the secretary of my desire to discuss the paper, I was not called on to do so. I therefore wish to say a few words here concerning Dr. Pierson's experiments.

I consider the strength of the gas used, not less than 1,500 parts to one million of air, far too strong. This amount could hardly have any curative action and would eventually and surely prove fatal to the rabbits. The gas was about 300 times stronger than I am in the habit of using, viz., about five parts per million of air. It is imperceptible to the taste or smell below three parts per million of air as investigated by the U. S. Bureau of Mines in the Smedley Smelters Commission. No object can be gained by adding active irritation to tuberculous lungs and it must detract from its curative value. In addition to this, each treatment averaged seven hours a day! My patients take from 3 to 5 inhalations a day varying from 15 to 20 minutes, and with intervals of at least two hours. Why could not this same method of treatment be applied to rabbits?

Even when the gas is exceedingly weak and imperceptible, it causes irritation if inhaled too long, for I remember leaving a tank one evening near my desk, where I was occupied for about two hours, when I noticed that my throat and trachea felt very

dry, hot, and burning. I examined the tank carefully and noticed a very slight leak. After removal of the tank, these symptoms quickly subsided. Therefore to subject rabbits to sulphur dioxide gas 300 times stronger than used by me on human beings, and for seven hours a day instead of one hour a day, cannot but cause irritation and thus vitiate any attempts to discover any curative value. I hope Dr. Pierson will in future so modify his experiments as to eliminate any unnecessary irritation to the lungs.

In conclusion I wish to state that:

1. Sulphur dioxide is not irritating nor harmful if carefully used, as we know from the great number of men employed in its manufacture or use.[2]
2. In using it for tuberculous patients, only incipient cases should at first be selected for treatment.

THE INDUCTION OF GRADUAL, NORMAL, MENOPAUSE AFTER OVARIECTOMY.

BY ALBERT GROVES HULETT, M.D.,
EAST ORANGE, N. J.

ALL those who have had occasion to persuade a female patient to submit to either an ovarectomy or pan-hysterectomy know that the objections and questions raised by the patient are rarely, if ever, concerned with the physical risk of the operation, per se, but rather an expression of dread of various dire and terrible nervous and mental phenomena which she is convinced will follow the removal of her ovaries.

Though the physician knows that the mental and nervous reactions will not be calamitous, he fully appreciates the probability that they will be distressing and annoying to the patient as well as to himself. Unless a potent prophylactic be in his possession he is not to be blamed if he hesitates to urge these operations, since without such an agent he would be unable to assure the patient truthfully that her fears were groundless, and might well question whether the treatment might not, in the end, prove almost as disturbing as the disease before him.

Having carried a number of patients through the displeasures of an abrupt surgical menopause, our sympathies were aroused and we decided to seek a method which would enable us to prevent these developments. This course was first embarked upon more than six years ago, so that the results and deductions which we shall state in this article may be said to have withstood a very fair clinical test.

The scientific basis for our method will bear a brief recital at this point even though the facts be well known to all. It is an accepted doctrine that the underlying cause of the phenomenon commonly known as the menopause is a change in the functional activity of the ovaries whereby ovulation ceases and an undoubted alteration in their internal secretion occurs. This alteration in activity, in the well woman, is a gradual process covering many months and the cessation of menstruation and mild nervous symptoms which it induces constitute the normal menopause or climacteric.

The deduction naturally follows that the more violent nervous disturbances so often induced by ovariectomy can be accounted for by the abrupt and complete removal of the internal secretion of the ovary to which the body of the woman is subjected by that operation.

It seemed logical to infer that by the adoption of a method whereby this secretion would be gradually removed from the body over a term of months, a normal menopause could be simulated in these patients and the usual difficulties avoided. Should this attempt succeed the chief dread of the patient facing ovariectomy and the misgivings of the physician would vanish together, and the operation could then be urged upon the patient whose disease demanded it with the assurance that her health would not be seriously interfered with.

Realizing the proven worth of thyroid feeding in cretinism, ovarian feeding seemed to promise much. Since by this method we sought to accomplish a gradual diminution of ovarian secretion in the body fluids, the decision as to the initial daily dose, the rapidity and rate of its decrease, and the duration of the treatment was the first and principal problem to solve.

Immersed in an active practice, without means for extended research in these determinations, we resorted to clinical trials, and therefrom very shortly evolved the routine which for nearly six years has been followed in all cases where both ovaries have been subjected to surgical removal. Without exception, these women have escaped any untoward nervous or physical derangement which might be inferred as due to the ovariectomy, and, aside from the normal physical weakness which obtains in the first few weeks following any abdominal operation, have left the hospital to resume their normal life habits without restraint. A recitation of numerous cases might be appended, but since all have been identical in the main particulars this tabulation is omitted here and an outline of the routine deemed sufficient.

Starting on the fifth day after operation the patient is given five grains of ovarian substance in tablet form, four times daily. This dosage is continued for one month. For the next two months three doses of five grains each are administered daily. Throughout the succeeding three months the dose is three grains three times daily, during the seventh and eighth months the patient takes three grains twice daily, and, during the ninth month two grains twice daily. In the tenth month two grains are taken each night upon retiring, in the eleventh month two grains upon retiring, on alternate nights, and in the twelfth month, two grains, upon retiring, every fourth night. This completes the medication.

The rationale of the treatment is carefully explained to the patient, and if she be a married woman, to her husband also. This serves to secure her cooperation and faithful adherence to the schedule as well as to prove to her that a reasonable and potent prophylactic is being given.

In the case of the married woman, the resumption of normal sexual relations is advised as soon as her surgical recovery will permit, and in all cases the resumption of her normal habit of living is urged upon the patient.

Extract of corpus luteum and entire dried ovarian substance have been employed, individually, in many parallel cases, and alternately administered in others, without detecting any essential difference in effect or potency.

No claim to originality is offered for the method outlined above; and, though we stumbled upon it by deductive reasoning and knew of no other physician, by name, who was employing the same method, we had assumed that the principle was generally known and must consequently be in more or less general use. However, some two weeks ago, when in consultation with a New York physician of large experience and ability, I casually mentioned that, though the patient we were considering had submitted to a panhysterectomy some two years ago, prophylactic feeding had prevented any reflex disturbances, he declared his ignorance of the method and its principle. Upon receiving a verbal account very similar to the above, he inquired why it had never been published. While I do not feel at liberty to publish his name, the reader may blame him for the submission of this article.

If I shall induce only one other physician or surgeon to try the scheme outlined above my effort will be well rewarded.

20 Hawthorne Avenue.

Medicolegal Notes.

The Reading of Medical Works to Expert Witnesses.—In an action against a hospital and physicians for malpractice in the treatment of an impacted fracture of the right hip joint and dislocation of the joint, the Montana Supreme Court held it improper for plaintiff's counsel to include in a question to physicians testifying on his behalf statements from text books on medical subjects, and that the admission of such questions is reversible error. "Experts are permitted to give their conclusions because of their presumed knowledge of subjects with which the ordinary layman or juror is not conversant. These opinions may be the result of their actual experience, or because of theoretical knowledge based upon special study of the subject. The testimony given by them is necessarily in the nature of a conclusion in most instances, and likewise is largely in the nature of hearsay. For a witness whose fitness is thus determined to be permitted upon his direct examination to merely state that he agrees with the text of a certain text writer is in effect to permit the reception in evidence not only of the expert's opinion, but likewise to permit the unsworn statement of another to go to the jury without opportunity for cross-examination. It is permissible, and perhaps necessary and advisable in most instances, for the expert to state his experience, knowledge and other qualifications, even stating the sources of his knowledge; but we are not inclined to extend the rule to permit the introduction of statements of text writers upon medical subjects as part of the direct evidence." The court distinguishes between this ruling and its holding in Emerson v. Butte Electric Ry. Co. (1912), 46 Mont. 454, that the trial court did not abuse its discretion in permitting counsel for the plaintiff to read to a physician, *on cross-examination*, an excerpt from a medical work, and asking him whether he agreed with the statement therein made.—Schumacher v. Murray Hospital (Mont.), 193 Pac. 397.

X-ray Photographs in Evidence.—In an action against a dentist for malpractice in extracting a tooth, the admission of the testimony of an *x*-ray operator, who did not qualify as an expert dentist, as to the condition of the bone after the extraction as shown by the *x*-ray photograph, was held error prejudicial to the defendant.—Saas v. Hindmarsh, 184 N. Y. Supp. 467. In an action against a hospital and physicians for malpractice in the treatment of a fractured hip, it was held error to refuse to instruct the jury, at the request of the defendants, that they could not consider any reference to the defendants' failure to take an *x*-ray picture of the patient's hip unless the plaintiff had proved that it was usual and customary under the circumstances for ordinary skillful and careful physicians to take such a picture.

Testimony to the effect that one medical witness did so in all cases, but did not know of the practice of others in that regard, was not sufficient to show negligence. In the present case the defendants did not use the *x*-ray until the thirty-sixth day, and the physicians said they had no reason to suspect the existence of the fracture, and that, even if they had discovered it earlier, there would have been no change in the treatment, under the conditions.—Schumacher v. Murray Hospital (Mont.), 193 Pac. 397.

Defendant in Malpractice Case May Testify That He Used His Best Judgment and Skill.—The Iowa Supreme Court holds that, in an action against a surgeon for malpractice in the treatment of the plaintiff's fractured leg, the testimony of the defendant, on redirect examination by his counsel, as to whether he had given the plaintiff the benefit of his best judgment and skill, was admissible, and its exclusion was prejudicial error. The court said: "The defendant was asked whether he used his best judgment. No one else could testify as well as he whether he did or not. Of course, if he had said he did, it would not be binding on the jury necessarily, but they were entitled to the evidence. We are of opinion that there was prejudicial error in the ruling." A medical witness in the case having testified that the effect on the foot of improper placing of the splints and cast would be very painful, it was held that a question to the witness whether the patient could endure such pain without a sedative and without the loss of any weight was objectionable, as calling for a conclusion.—Asnes v. Scanlon (Iowa), 179 N. W. 869.

Physician's Testimony that Injury Could Have Aggravated Disease, Competent.—A physician having testified in a personal injury case that: "It would be possible for the plaintiff to recover from an operation for removal of stones from the kidneys, and the injuries to her back alleged to have been received by reason of the accident could have aggravated or brought about the diseased condition in which her kidneys were shown to have been after the accident," it was held that this answer was not objectionable on the ground that it related, not to probabilities, but to possibilities, or was speculative and referred to conditions too remote. The physician was giving his opinion of the immediate effect of an injury such as the one described by the plaintiff upon her condition at the time of the accident.—El Paso Electric Ry. Co. v. Jennings, Texas Civil Appeals, 224 S. W. 1113.

Regular Visits Under Health Policy Provision.—In an action on a health policy requiring that the insured should be "continuously confined within the house, and therein regularly visited at least once a week," it was held that the meaning of this clause is that the physician must be weekly in attendance upon the insured; and it was sufficient that the physician made two calls in person at insured's home during his illness from February 14 to March 15, and was kept informed as to the insured's condition by telephone, prescribing for him on the personal visits and telephone calls.—Bass v. Pioneer Life Ins. Co. (Mo. App.), 227 S. W. 639.

THE PRESENT STATUS OF SEX DETERMINATION.

CERTAIN biologists have maintained that it is possible to determine the sex of the embryo by bringing certain influences to bear during its development. At the beginning of embryonal development there is only a genital outline which later on becomes precise, so that it has been supposed by some that before the fourth week of intrauterine life the sex is indifferent and by appropriate means the evolution of the embryo could be regulated for male or female offspring, and much experimental work has been done in this respect.

Bordage experimented with *Carica papaya;* by cutting the stem of a one-year-old male carica before budding time he transformed it into a female plant. But the majority of experiments have been carried out on animals with the object of influencing the product of conception by acting on it through maternal nutrition. Born and Junge overfed tadpoles and were able to obtain respectively 78 per cent. and 95 per cent. females, instead of the usual 54 per cent. to 61 per cent. Similar results have been obtained in caterpillars by both Treat and Giard. Cuenot experimented with albino rats. He divided the animals into two groups. The first were overfed, the second underfed, and then calculating the percentages of males and females born in the two groups, he noted a slight excess of females in the overfed animals, but the difference was very small. According to Landois, it is enough to transport the eggs laid in the alveoli of the working bees to those of the males in order to give rise to males, while the inverse likewise occurs. This statement has been denied by Sanson and Bastian. Geddes and Thompson believe that abundantly fed sows give birth to more females than males. De Kerhevé found that perfectly fed *Daphnia Psittacea* will give parthenogenic ovi, all of which will develop females, while Bernard noted that in the Apodidæ bad nutritive conditions resulted in a tendency to hermaphrodism in the offspring which constitutes a step toward the production of male products. Giron experimented with three hundred ewes; 50 per cent. of them were well fed and were covered by young rams, the other 150 were underfed and covered by old rams, with the result that the former gave issue to 60 per cent. females, the latter to 40 per cent. females.

Two observers have attempted to apply this experimental work to man, especially Orchansky, who maintains that maternal overfeeding will favor the development of female offspring, while Schenck of Vienna holds that the inverse is true. The results obtained by other investigators proved that both these observers were in the wrong and Schenck's theory was lamentably wrecked by the great publicity given it by the author. It is, for that matter, difficult to conceive how the nutrition of the reproductive cells can be acted on, since, in point of fact, nothing proves that nutritive plethora reacts on the genital cells. The birth statistics, according to social classes, are interesting from this viewpoint, because the number of female and male offspring should vary according to the extent of misery or prosperity of the parents. Now, in reality, the difference is minute. In France, according to Martin (Thèse de Paris, 1912), 115 boys to 100 girls are born to the poor and 104.5 girls to the well-to-do. On the other hand, Pennet, in 1901, published the results of the statistical findings of the sexes in London, and found that female births were more numerous than male in the poorer classes. Finally, how can this theory be maintained since, as Rauber has shown, in children born in extrauterine pregnancy where the conditions of nutrition are certainly unfavorable for the fetus, the two sexes break fifty-fifty. Therefore, this observer assumes that the sex is already formed in the ovum and Cuenot is of a like opinion, believing that the sex is already determined at the time of fecundation of the ovum at the latest.

Further experiments have destroyed the hypothesis of the effective part played by alimentation on the determination of the sex. King experimented with tadpoles, divided into four groups. One group was fed on meat with 49 per cent. female offspring; another group was fed on cereals and gave 54 per cent. females; the third lot received a mixed diet and gave 46 per cent. females, while the fourth group was fed on the yolks of eggs and the result was 60 per cent. female offspring. The alimentation in these experiments influenced the weight, size, and color of the offspring, but not the sex. Heapes implanted the ova of an Angora rabbit fecundated by an Angora rabbit into a female Belgian rabbit fecundated by a Belgian male rabbit. The result was that the litter was composed of two Angora and four Belgian rabbits. Therefore, the mother exercised no influence over the characters of her products of conception.

Robinson and Régnault were the promoters of the theory of sex determination by adrenalin. The former observer noted the influence of adrenalin on the determination of the sex by the exhibition of this drug to women with uncontrollable vomiting of pregnancy, and he maintained that in order to have a male child, adrenalin should be given to

pregnant women, while those with nutritional disturbances with vomiting and pigmentation showing an inferiority of their suprarenals will give birth to female children in 100 per cent. of the cases. *A priori* it does not seem scientific to admit that a condition as physiological as the determination of the sex of a child should be subject to pathological factors like hypofunction of an endocrine gland. As to the part played by choline in the production of sexes it has not been extensively studied and is at least obscure, not to say problematical.

RELATIONSHIP BETWEEN GRAVES' DISEASE AND TUBERCULOSIS.

THAT there is any causal connection between exophthalmic goiter and tuberculosis is most improbable and when we speak of a relationship between the two affections it must be understood as hypothetical rather than demonstrable. Common to both are tachycardia and fever, emaciation, diarrhea, and vasomotor disturbances, but this syndrome is not peculiar to these two affections. There is also the coincidence of a peculiar eye in each disease, which while by no means identical has something in common—luminous, moist, etc. Steck, who writes on this subject in the *Schweizerische medizinische Wochenschrift* for June 9, 1921, li, 23, says that when a tuberculous subject has a typical exophthalmus it is of course possible that he has a hyperthyroid component. Poncet indeed pointed out that tuberculous toxication sometimes causes enlargement of the thyroid, perhaps as a part of a defense reaction. On the other hand, histological studies of many thyroids of tuberculous subjects have failed to show a single case of the alterations which appear in typical Graves' disease. But it has been noted that the thyroid in these cases is never normal —that it may exceptionally be tuberculous but almost invariably is sclerotic. Now, if in a defense reaction developed against tuberculosis the thyroid is disorganized, we can perhaps understand why the pictures of tuberculosis and Graves' disease may largely coincide, and why tuberculosis may be the occasion for a picture of hyperthyroidism of a special type. We say that the tuberculous toxin causes this or that symptom without much effort to explain the mechanism; but if it stimulates the thyroid function we have a ready explanation of some of the symptoms of tuberculosis—tachycardia, low blood pressure, slight fever, the tuberculous eye, and vasomotor phenomena, as the blush on the cheek, part of the tendency to perspire, etc.

This sounds plausible, but is there not some catch in it? Such an explanation of early tuberculosis, including so-called pretuberculosis, is almost too simple. If true, it would not have escaped the older clinicians. Doubtless it is not difficult to isolate a type of tuberculosis with hyperthyroidism but there is tuberculosis without this component and Graves' disease without any tuberculous factor.

The author quotes authorities to prove that in a large material of typical tuberculosis, fully developed Graves' disease is as good as absent. This leaves, then, the association of the bacillary disease with mild and abortive Graves' disease or, as some term it, "basedowoid," which is as far as we can go at present without something more than clinical evidence. The author has made use of a method of comparative blood testing which he describes at great length which seems to demonstrate that the tuberculous subject's blood is quite free from certain substances found in hyperthyroid blood of any degree. The blood of any subject with Graves' disease acts as a synergist to adrenaline in producing vascular contraction, while tuberculous blood is, under all circumstances, quite free from this substance. The petty or minor basedowism of the tuberculous is therefore illusional and due to other factors. The author learned only after he had reached this conclusion that his finds and conclusions were in thorough accord with work recently published by Chvostek.

PSEUDOTUBERCULOSIS DUE TO DISEASE OF THE UPPER AIR PASSAGES.

DURING the late war the French physicians had considerable to say of a false tuberculosis encountered in recruits, which very closely simulated the genuine condition but was found to improve on the correction of intranasal deformities, sinus disease, and other anomalies of the upper air-food passages. In the *Journal de médecine et de chirurgie pratiques* for March 25, 1921, cviii, 6, Festal gives an elaborate account of the syndrome in question. The author states that it was well enough known before the war, but that the latter focused the eyes of the profession on it. Sergent found that many subjects rejected as tuberculous or suspects were of this type, which was moreover very common.

The resemblance to the early stage of tuberculosis of the lungs was often startling—slight temperature rise, emaciation, lassitude, spasmodic cough with profuse expectoration in the morning on waking, and even physical signs suggesting apical lesions. Of the two resources which might be expected to diagnosticate or exclude tuberculosis even the *x*-ray seemed noncommittal; only the bacteriological examination was frankly negative. The *x*-ray plate showed at times the absence of normal transparency of the apex with or without a suspicious hilus shadow. Auscultation and percussion gave the signs commonly encountered in early apical tuberculosis, such as lessened breathing, prolonged expiration, and slight dulness. The research for Koch's bacillus continued to be absolutely negative in the face of all subtleties of resource for bringing out the latter. In the course of a systematic examination the patients were found to present nasal obstruction, hypersecretion from the nasal passages which was at times purulent, empyema of some one or more of the sinuses, adenoid hypertrophy, and in some cases atrophic rhinitis. The patients attributed these troubles to tobacco and so were not especially

concerned about them. Indeed, they seem to have given them very little inconvenience. The rhinologist in examining these cases learned to look into the nasopharynx at the outset and the peculiar conditions encountered there sufficed to exclude for the time the suspicion of tuberculosis. There was, however, always the possibility of supervention of the latter.

Lemoine and Sieur once placed on record the physical signs encountered in the lungs of mouth-breathers irrespective of the causation. These sufficiently resemble those of beginning tuberculosis, and the author frankly admits that he does not attempt to differentiate by physical signs alone. One should proceed at once to the bacteriological diagnosis, but should this prove negative one cannot always straightway exclude tubercle. Difficulty of radiological differentiation has already been mentioned, and the author would place his main reliance on the effects of treatment of the nose and nasopharynx. But while in one patient the change for the better is at once apparent, in another two or three months may elapse before the benefit is realized. There is a third type in which, after a clearing up of the upper passages, the patient's chest shows no improvement at all, and here we have to regard him for the time being as actually tuberculous or perhaps as having recovered from tuberculous lesions with residual sclerosis, etc., until time comes to our aid.

The Great Unstable.

The well known medical littérateur of Paris, Voivenel, has written a paper with the title *Les Grands Inquiets*, which is commented on in *La Presse Médicale* for June 29, 1921, xxix, 52. Unstable may not be a very good rendering of the French *inquiet*, but it conveys the author's meaning better than any other, for such adjective substantives as restless, anxious, fearful, uneasy, etc., would not answer at all in this connection. Some disequilibrium or want of steadiness of the nervous system is only too common in modern civilized man. The author limits himself to the constitutionally unstable and in the present connection concerns himself only with intellectual subjects. One might say that authors and artists, to succeed, must be unstable in order to express or visualize the emotional states of others. A vivid imagination which goes with disequilibrium makes inevitable much fanciful suffering which may be harder to bear than actual strokes of ill fortune. The unstable live in an atmosphere of fear. Some of them have been tuberculous and the disease has augmented the natural instability. The author cites among authors Schiller and Prosper-Merimée, and among artists and musicians Watteau, Schubert, and Mozart. In many without any tuberculous factor life has been one long stretch of anguish. This list, which is a long one, comprises Pascal, Rousseau, Hoffmann, Poe, Baudelaire, Verlaine, Byron, Shelley, Dostoyevsky, et al. Both of these lists could be greatly extended. Characteristic of the unstable is the recourse to drink and drugs in the attempt to bridge over depressive and anxious periods.

Present Status of the Exudative Diathesis.

Before the years of the war pediatric journals contained much on the socalled exudative diathesis of Czerny, a condition which overlaps a number of other alleged diathetic affections such as scrofula, spasmophilia, milk intolerance, etc. Marie in *La Presse Médicale* for June 25, 1921, xxix, 51, claims that this diathesis was long ago described in France by Bazin and Besnier. The characteristic lesion is the socalled "milk-crust" of the nursling, while intertrigo belongs under the same head. After two years the nursling symptoms have disappeared—have been outgrown, but others take their places. Niemann, a recent writer, disagrees with Czerny concerning the later symptoms and regards strophulus and urticaria as essential to the diathesis. The mucosæ seem more compromised than the skin in later childhood and recurrent angina, bronchitis with asthmatic crises, and false croup are tokens that the diathesis is present. The extreme nervous irritability of these children may appear as spasmophilia of the latent type, although Niemann seems to think that constitutional neuropathy amenable to psychotherapy is the neurotic component. Doubtless this diathesis shades into vasomotor instability also, with pictures of vagotonia. Another constitutional anomaly overlapped is status lymphaticus. That so many different conditions overlap one another is an argument against setting up concrete pictures of diatheses. The most striking feature in practice concerning Czerny's diathesis is the milk intolerance. Why not let it go at that without attempting to build up a constitutional anomaly around it?

News of the Week.

Cholera Decreases in Volga District.—The Moscow correspondent of the New York *Herald*, says there has been a decrease in the number of cholera cases in the Volga district, there having been 22,000 cases reported during July, as against 42,000 in June. A bill was introduced into the United States Senate on August 19 directing the President to use $5,000,000 worth of medical supplies of the War Department for relief work in Russia.

Care of Disabled Soldiers to Rest With War Risk Bureau.—Surgeon General Hugh S. Cumming has recently made a statement recalling that the care of disabled soldiers did not constitute a part of the Public Health functions of the Service but was undertaken through patriotism and because the Service was the only public agency that had an organization and hospitals available when the need came. Later its assignment to this duty was made a matter of law. From March 3, 1919, when this law went into effect, to May, 1921, when the hospitalization and care of nearly half of these patients were transferred to the War Risk Bureau, the number of former military patients in charge of the Service increased from 990 to 25,000, with indications of still further increase. From the first the number increased faster than the government hospitals could be extended and the Service was compelled to place about two-thirds of its patients in private hospitals under contract. On May 1, 1921, the number so placed was 10,500. Responsibility for these patients has been restored to the War Risk Bureau.

The Public Health Service, if bills now pending become law, will merely render hospital care to those whom the War Risk Bureau assigns to it. This action will enable the Public Health Service to turn a much larger share of its energies to its traditional duties.

Typhoid Fever in New Jersey.—All the available forces of the State Health Department have been sent to Burlington County, New Jersey, where there is a serious epidemic of typhoid fever. It was reported in Trenton on August 20 that there are more than two hundred cases of the disease in twelve towns of the county. The origin of the outbreak has not yet been determined.

Typhus Suspect Holds Up Liner.—A suspected case of typhus fever in the second cabin of the Cunarder *Aquitania*, which arrived in quarantine at the Port of New York on August 20, caused the vessel to be detained for eight hours. The patient and sixty-one passengers in the section she occupied were transferred to Hoffman Island for observation.

Colorado Hospital for War Veterans.—Under an executive order signed by President Harding, the Veterans' Bureau has taken over the naval tuberculosis hospital at Fort Lyons, Las Animas, Col. The institution has a capacity of 780 beds and will be used for war veterans suffering with tuberculosis.

Municipal Hospitals Open to Obstetrical Cases.—Bird S. Coler, Commissioner of Public Welfare of New York City, announces that he has decided to open the city hospitals to confinement cases as a means of relief to families with an income ranging between $2,500 and $5,000 a year. Under the new plan the charge at the city hospitals will be $2.50 per day.

Drug Addiction and Prohibition.—Figures compiled by the Department of Public Welfare of the City of New York show that in 1918 there were 116 addicts under the care of the city hospitals, 339 in 1919, and 493 in 1920. For the first six months of this year there were 337 cases. In 1918 the department cared for 1,145 cases of alcoholism, and in 1920 there were 1,024 cases. Up to July of this year there have been 567. The report states that certainly prohibition has not lessened the number of alcoholics treated in the city hospitals while the number of drug addicts has increased.

Army Dental School.—Major General Merritt L. Ireland, Surgeon General of the Army, addressing the Military Dental Surgeons at their recent meeting in Milwaukee, announced that he expects to have established by next January a training school at Washington and corps schools at various other points, to give the necessary training to about 800 dental officers a year. He hopes to build up an organization that will be large enough to take care of the dental work of an army of 4,000,000 men.

School of Public Health in Harvard.—Plans for the organization of a School of Public Health in Harvard University, with the aid of an initial gift of $1,750,000 by the Rockefeller Foundation, have been announced by the University and the officers of the Foundation.

Health Tests Sought for Children at Work.—Health Service for boys and girls of fourteen to sixteen years who have left school to work in factories is recommended by Dr. H. H. Mitchell in a report to the National Child Labor Committee just made public. The report urges the establishment, either by health or school authorities, of a system of periodical physical examinations for working children. According to Dr. Mitchell's plan the examinations would be followed by measures to correct defects and to provide adequate physical education through continuation schools.

Red Cross Hospital Burned.—On the night of August 14 fire destroyed two buildings occupied by the Red Cross child health clinic in Salonica, Greece. Dr. Russell Stewart Wingfield of Richmond, Va., medical head of the Red Cross unit in that place, was seriously burned. There were no casualties among the nurses and children.

Hospital Notes.—Plans have been filed for the enlargement of St. Justice Hospital for Children on Denis Street, Montreal, which will cost about $220,000. Provision is also made for a new dispensary building.—The new Missouri, Kansas, and Texas Railway Employees' Hospital at Dallas, Texas, built at a cost of $250,000, will be opened to receive patients about September 1.—Plans for a new building for the Jamaica (Long Island) Hospital are about completed and ground will be broken in the near future. The new structure will cost approximately $500,000 and will have 122 beds.—The recent drive for funds for the Huntington Hospital, Huntington, L. I., has netted over $30,000. Of this sum $25,000 is to be used for an extension to the present hospital building.—A fire in the Norfolk (Neb.) Hospital on August 15 caused damage to the buildings estimated at $5,000.

Dr. Helen L. Palliser has tendered her resignation as health officer at Poughkeepsie, a position she has held for the past four years, to take effect January 1, 1922.

Activities of the Medical Women's National Association.—A statement recently made by Dr. Elizabeth Bass, president of the Medical Women's National Association, defines the objects of that organization. She says that medical women are not organized for scientific purposes—the American Medical Association of which they are all members covers that—but for movements in the interest of women. The association will keep a list of medical colleges which admit women and of hospitals in which women may become internes, and of hospitals which afford the best opportunities along certain lines. Another piece of work which the association has in view is to compile a history of medical women in America. It is estimated that there are between five and six thousand women doctors in the United States of which more than six hundred belong to the Association. Efforts are being made to bring as many women doctors as are eligible into the organization.

Charitable Gifts and Bequests.—The will of Mrs. Fannie J. Byrnes makes bequests of $5,000 each to the Hahnemann and Flower hospitals, New York City.

By the will of the late Mrs. Abigail A. Geissinger of Danville, Pa., a large fortune is bequeathed to the George F. Geissinger Memorial Hospital for maintenance. Prior to her death Mrs. Geissinger donated $2,000,000 for the erection, equipment and endowment of the institution.

By the will of the late Clara Snyder of Philadelphia the sum of $100 is bequeathed to the Frankford Hospital for furnishing two rooms.

International Congress on Ophthalmology.—Diplomatic officers of the United States in foreign countries have been instructed to communicate to the governments to which they are accredited an invitation by the American Ophthalmological Society, the Section on Ophthalmology of the American Medical Association, and the American Academy of Ophthalmology and Oto-Laryngology, to participate in an international congress of ophthalmology to be held under the auspices of those societies in Washington, D. C., April 25-28, 1922.

Medical Society Elections.—THE CENTRAL PENNSYLVANIA HOMEOPATHIC MEDICAL SOCIETY, at its quarterly meeting held in Columbia, August 13, 1921, elected the following officers: *President,* Dr. G. A. Sayres, Lancaster; *secretary-treasurer,* Dr. C. G. Swartz, Lancaster.

THE CHATTANOOGA VALLEY MEDICAL AND SURGICAL ASSOCIATION, at its annual meeting held in Warm Springs, Ga., July 15, 1921, elected the following officers for the ensuing year: *President,* Dr. F. K. Boland, Atlanta; *Vice-President,* Dr. Marcus Skinner, Selma; *Secretary-Treasurer,* Dr. W. J. Love, Opelika, Ala.

THE NORTH DAKOTA MEDICAL ASSOCIATION, at its annual meeting held in Fargo, May 17, 1921, the following officers were elected for the ensuing year: *President,* Dr. H. E. French, Grand Forks; *President-Elect,* Dr. E. P. Quain, Bismarck; *First Vice-President,* Dr. W. C. Fawcett, Starkweather; *Second Vice-President,* Dr. H. J. Rindlaub, Fargo; *Secretary,* Dr. H. J. Rowe, Casselton; *Treasurer,* Dr. J. P. Aylen, Fargo.

THE CHICAGO MEDICAL SOCIETY, at its annual meeting held June 16, 1921, elected the following officers for the ensuing years: *President,* Dr. John S. Nagel; *Secretary,* Dr. John R. Harger; *Counsellors at Large,* Dr. J. H. Way, Dr. Clara Seippel, Dr. Thomas P. Foley, Dr. Edward H. Oschner and Dr. H. F. Bruning. *Alternate Counsellors at Large,* Dr. N. S. Davis, Dr. N. White, Dr. A. Haeffner, Dr. W. S. Bougher, and Dr. M. Janpolis.

THE NEURO-PSYCHIATRIC SOCIETY OF MILWAUKEE, at its annual meeting held June 17, 1921, elected the following officers for the ensuing year: *President,* Dr. F. C. Stanley; *Vice-President,* Dr. W. G. Wegge; *Secretary-Treasurer,* Dr. C. W. Roberts.

THE OHIO COUNTY (W. VA.) MEDICAL ASSOCIATION, at its annual meeting held in Wheeling, June 3, 1921, elected the following officers for the ensuing year: *President,* Dr. D. A. McGregor, Wheeling; *Vice-President,* Dr. Turner Morris; *Secretary,* Dr. M. B. Williams; *Treasurer,* Dr. W. S. Fulton.

THE AMERICAN ASSOCIATION FOR THE STUDY OF THE FEEBLE-MINDED, at its forty-fifth annual convention held in Boston, May 31, 1921, elected the following officers for the ensuing year: *President,* Dr. Joseph H. Ladd, Slocum, R. I.; *Secretary-Treasurer,* Dr. Benjamin Ward Baker, Manchester, N. H.

THE NEW JERSEY STATE BOARD OF MEDICAL EXAMINERS, at a meeting held in Asbury Park, July 7, 1921, elected the following officers: *President,* Dr. James J. McGuire, Trenton; *Secretary,* Dr. Alexander Macalister, Camden; *Treasurer,* Dr. Joseph H. Bryan.

THE LEHIGH VALLEY MEDICAL ASSOCIATION, at its forty-first annual meeting held at Delaware Water Gap, Pa., July 29, 1921, elected the following officers for the ensuing year. *President,* Dr. A. C. Herman, Lansdale; *Vice-President,* Dr. M. C. Rumbaugh, Kingston; *Secretary,* Dr. Alexander Armstrong, White Haven; *Assistant Secretary,* Dr. R. Batchelor, Palmerton; *Treasurer,* Dr. D. H. Keller, Bangor.

THE MEDICAL WOMEN'S NATIONAL ASSOCIATION at its annual meeting held in Boston June 6 to 8, 1921, elected the following officers for the ensuing year: *President-Elect,* Dr. Grace Kimball, Poughkeepsie, N. Y.; *First Vice-President,* Dr. Mable R. Noble; *Second Vice-President,* Dr. Martha Welpton, San Diego, Calif.; *Third Vice-President,* Dr. Sue Radcliff, Yonkers, N. Y.; *Recording Secretary-Treasurer,* Dr. L. Rosa H. Gantt, Spartanburg, S. C.; *Corresponding Secretary,* Dr. Isabelle T. Smart, New York City. *Counsellors:* Dr. Bertha Van Hoosen, Dr. Ellen C. Potter, Dr. Flora Pollack, Dr. Mary T. Greene, Dr. Margaret F. Butler, Dr. Elvenor Ernest, Dr. Martha Tracy.

Obituary Notes.—Dr. GUSTAV MANN, a graduate of Edinburgh University, Scotland, died at Tampico, Mexico, July 18, at the age of fifty-six years.

Dr. ROBERT T. FRENCH of Rochester, N. Y., a graduate of Buffalo Medical College in 1888, died suddenly of heart disease August 18, at the age of fifty-seven years. He was a member of the American Medical Association and the Rochester Academy of Medicine.

Dr. HOWARD WILLIAM LONGYEAR of Detroit, Mich., a graduate of the College of Physicians and Surgeons, New York, in 1875, died suddenly on June 2, at the age of sixty-seven years. He was a member of the American Surgical Society, the American Gynecological Society, consulting physician to the Women's Hospital, consulting gynecologist to the Providence Hospital, and consulting surgeon to the Harper Hospital.

Dr. ELIJAH GREEN of Martinsville, Ind., a graduate of the Indiana Medical College in 1876, died on June 7, at the age of seventy-one years.

Dr. CHARLES STOCKERT of Lincoln, Neb., a graduate of Rush Medical College in 1893, died on May 30, at the age of fifty-two years.

Dr. UNION WORTHINGTON of Salt Lake City, a graduate of Tulane University School of Medicine, died in Santa Monica, Cal., May 31, at the age of fifty-nine years. He was formerly demonstrator in anatomy at the Gross Medical College, Denver, and later a member of the staff of St. Mark's Hospital, Salt Lake City, and chief surgeon of the Oregon Short Line Railway.

Dr. JOHN BRYANT of Independence, Mo., died in Berkeley, Cal., on July 15. He was graduated from the Washington University Medical College, St. Louis, in 1865 and from Jefferson Medical College, Philadelphia, in 1866.

Dr. GEORGE F. BAER of Pittsburgh, a graduate of the Hahnemann Medical College and Hospital, Philadelphia in 1905, died on July 10, at the age of thirty-six years.

Dr. EDWIN L. BEEBE died at his home in Buffalo on July 17, at the age of fifty-one years. He was graduated from the College of Physicians and Surgeons, New York, in 1893. He was made captain of the 74th New York regiment in 1904, and was

raised to the rank of major surgeon in 1914. He was with the 12th infantry of New York during the World War. On his return to Buffalo at the close of the war he was made city physician.

Dr. CLARA ROGERS RUTTER, a graduate of the Boston University School of Medicine in 1879, died at her home in Lawrence, Mass., July 15, at the age of sixty-seven.

Dr. ARCHIBALD A. C. FAIRBAIRN of Minneapolis, a graduate of Queens University Faculty of Medicine, Kingston, Canada, died in a local hospital on July 9, at the age of seventy-eight years. He was formerly chief surgeon for the Northern Pacific Railroad.

Dr. WILLIAM E. KEILY, a graduate of the Medical College of Ohio, Cincinnati, in 1877, died at his home in Cincinnati on July 14, at the age of seventy-two years. He was a former president of the Cincinnati Academy of Medicine.

Dr. LUCIEN C. MCELWEE of St. Louis, Mo., a graduate of the Missouri Medical College, St. Louis, in 1882, was killed in a street accident on July 3. He was fifty-eight years of age.

Dr. ROBERT BANCKER TALBOT of New York City, died of pneumonia at Racquette Lake, N. Y., July 16, at the age of sixty-nine years. He was graduated from the College of Physicians and Surgeons, N. Y., in 1877. He was associate surgeon at the Women's Hospital.

Dr. GEORGE WAYLAND DODGE of Moravia, N. Y., a graduate of the New York Eclectic Medical College in 1894, met death by accident on July 7.

Dr. JAMES MIDDLEDITCH of Barneveld, N. Y., a graduate of the University of Buffalo College of Medicine in 1881, died of cancer of the liver on July 11, at the age of sixty-seven years.

Dr. PHILIP ERHARD of Syracuse, N. Y., a graduate of the Syracuse University College of Medicine in 1902, died on July 9, at the age of forty-four years.

Dr. MILTON BURR DAVIS, a graduate of the Long Island College Hospital in 1883, died on July 15, at the age of sixty-one years.

Dr. ELIAS GALLEY BROWN of Allaben, N. Y., a graduate of the College of Physicians and Surgeons, New York in 1895, died of cancer of the stomach in New York City, June 28, at the age of fifty years.

Dr. JOHN FRANK, retired, a graduate of the College of Physicians and Surgeons, New York in 1880, died at his home in Bayonne, N. J., July 19, at the age of sixty-five years.

Dr. JOHN J. DEFENDORF, Health Officer of Ionia, Mich., died after a brief illness on July 8, at the age of seventy years. He was graduated from the Detroit Homeopathic Medical College in 1872.

Dr. PHILIP ERHARD of Syracuse, N. Y., died after a brief illness on July 7, at the age of forty-four years. He was graduated from the Syracuse College of Medicine in 1902.

Dr. JOEL M. INGERSOLL of Rochester, a graduate of Bellevue Hospital Medical College in 1879, died in Canandaigua, N. Y., July 2, at the age of sixty-four years.

Dr. WILLIAM R. FRISBIE of Washington, D. C., a retired pension examiner, died at the Carroll Springs Sanitarium, July 3, at the age of eighty-five years. He was graduated from the College of Physicians and Surgeons, Keokuk, Ia., in 1880.

Correspondence.

THE PELLAGRA OUTLOOK.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The pellagra outlook is a subject of no small importance, not only to the South, but to the entire United States. This statement is fully warranted by the fact that for two centuries the disease has been regarded as a scourge in Italy and southeastern Europe, while they have found no positive means of arresting its progress nor have scientists been uniformly agreed as to the cause. Judging from the reports of the United States Public Health Service, there can be no question that pellagra is present in various sections, but the conditions at present are no different from what they have been for nearly ten years past.

The presence of pellagra at any point in this country is a blot; it is a shame that this Government is not so far qualified and authorized that it can step in and correct the supposed defects or deficiencies that are responsible for this disease. It is a social barrier, breaking up families by premature death; it is an economic disaster, interfering with production and manufacturing; it is a matter of vast hygienic and dietic importance, not only because of the present but for the rising generation. There is no telling what is likely or liable to follow the disordered condition of the nervous system to which pellagra gives rise. Such being the case, is there no indication, hope, prospect or possibility that we may find on the medical horizon the sign reading "This Way Out"? My impression is that within five years, with proper attention to the dietary, pellagra in the South would be only a matter of history. My first injunction would be to follow the directions given by McCollum, to secure more of the leaf food because it contains the essential protein or rebuilding material. But it possesses another and special value because the leaf is charged with a positive electrical current, while the root crops and stems are charged with negative current. Even a vegetable so simple as the onion, tested with the delicate galvanometer, shows a negative sign at the root, while at the top we have a positive sign. But this is not all, as the readers of this Journal may recall that I referred in my paper, "The Diet and Health" (MEDICAL RECORD, July 10, 1920) to the exceptional value of the mineral salts and protein in a dietary which included alfalfa, corn, and peas. The trouble with the dietary in the South is due to the lack of protein and mineral salts, but the mineral deficiency is of paramount importance as one of my correspondents, Dr. A. J. Johnson, of Pensacola, Florida, has demonstrated in the treatment of quite a number of cases suffering from pellagra. When the controversy first arose I inquired of Dr. Johnson what the outlook was, asking him to give me some data from his viewpoint, and here follows the reply:

> In reply to your inquiry relative to my experience with pellagra, will state, first of all, that so much interest being manifested concerning this disease—its increased prevalence and near pestilence and famine in the South, is about all "bosh," as I see it. As a matter of fact there *is* more of it in evidence just now simply because we see the "red flag" out, as it were—the erythema and other active symptoms during this season of the year—and a large per cent. of these mani-

festations will disappear as soon as the cool weather approaches and the "powers that be," health officers, will not need to bestir themselves very much, either. Other years have shown an increase in the number of cases to be followed next year by very little of it in evidence, and so on and so on.

Pellagra, like smallpox, has lost its terror to a great extent; few people die with it and many recover. It lacks a great deal of being a pestilence or plague. The South is fairly prosperous, especially west Florida, and distressingly healthful just now. I have studied and treated pellagra for at least twelve years, and at this time have under observation several cases at different stages, some chronic or recurrent and some recent cases. Acting upon your suggestion, early this summer, I have tried out a number of cases on the colloidal calcium treatment, and the results are all that could have been expected. All of the cases have shown decided improvement and one typical case is almost entirely well.

Mrs. H., 34 years of age, occupation, housewife, has for more than one year suffered with nervousness and indigestion which would not yield to treatment ordinarily given, and she tried a number of remedies. It was late this spring when the skin lesion appeared, thereby settling the question of diagnosis. She had pellagra, was sick with it a year ago, but nobody called it that, and this is typical of the disease—many get well spontaneously and some go on and develop serious symptoms. The skin lesion in this case was confined to the face and forearms. There was burning in stomach and in the extremities—neuralgic pains all over. She was in great distress and approaching insanity. There was acid salivary and skin reaction, with moderate knee-jerk. Could scarcely eat a thing. A few weeks of colloidal calcium and remedies having specific influence upon the chronic deviation made a decided change for better and there can be no doubt of an ultimate cure in a very short time.

Evidently, Dr. Johnson takes a practical view of the pellagra situation as it applies throughout the entire South.

A FEW FACTS, JUST TO KEEP THE RECORD STRAIGHT.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In a letter published in the MEDICAL RECORD, July 30, 1921, "As to Being Out of Step," I stated incidentally that "In my opinion Dr. Rooney is largely responsible for the chaotic conditions now existing in New York State, and New York City in particular, for the lack of a State law to enforce the Harrison act."

Dr. James F. Rooney, now president of the Medical Society of the State of New York, honors me by making a reply under the caption "Now It Can be Told" appearing in your columns, August 13, 1921, and after a brief introduction, proceeds "to recapitulate some of the history of narcotic legislation of recent years to show that this statement is false." Naturally I resent the implication of intentional misrepresentation, but I virtually expected it, and so far as personal considerations are concerned, shall content myself by recording a flat denial. That is more than Dr. Rooney has done in answer to Attorney Greenfield, his reply being nothing more than an adroit circumvention, begging the question. The charge of misrepresentation itself, however, is an important matter and, with your permission, I will proceed to show that my opinion was based upon considerable knowledge of the circumstances, and a fair deduction from the evidence known to me.

A man who tells the whole truth voluntarily may be lacking in tact, not to say discretion. Still, if Dr. Rooney has made up his mind to tell it, why doesn't he? He dismisses what happened in respect to action on his part this year up to the adjournment of the House of Delegates relating to pending narcotic legislation in these few words: "So far as securing an endorsement for any bill either on the floor of the House of Delegates or in the Council this year the facts are these: Both of these bills were referred to a reference committee of the House of Delegates, composed of Dr. Charles G. Stockton of Buffalo, chairman; Dr. T. J. Farrell of Utica, and others, who, after hearing the arguments upon these measures, referred the whole question to the House of Delegates. Even Dr. Mabbott may recall that it was I who made the motion to refer these bills to the Council for action."

Now I certainly did not state that my opinion was based upon Dr. Rooney's acts in so limited a field. He appeals to my recollection as to what happened on the floor of the House of Delegates. Fortunately, I am not compelled to rely entirely upon memory, as I was secretary of the New York County delegates sitting in the House and took copious notes, aided by which I afterwards made a report of the proceedings, which I read before the meeting of the Medical Society of the County of New York, May 23, 1921.

Dr. Rooney, as chairman of the Legislative Committee of the State Society, had appeared at legislative hearings and before the Governor, opposing the Fearon-Smith bill; he had endeavored to enforce a rule to suppress the voice of those who disagreed with him. He had sent out a circular letter to County Society secretaries and to members of the House of Delegates, which was largely an argument directed in opposition to the Fearon-Smith bill. In this letter he at least suggested the endorsement of the second Smith-Lord bill, when he described the Fearon-Smith bill as "so burdensome," etc., "whereas the Lord-Smith bill places no restrictions upon the practitioner of medicine that he must not already suffer under the Federal Law." His reply postcard gave no suggestion that he was opposed to both bills:

The Medical Society of the County of ..... favors the enactment into law regulating the use of narcotic drugs of the SMITH-FEARON BILL
the LORD-SMITH BILL
Remarks: .....
Secretary Delegate.

The actual report of his committee at the meeting took the usual course, as stated by Dr. Rooney, going to a reference committee, and was reported out as stated. This is where Dr. Rooney makes an important omission. My notes taken on the spot state that "Dr. Rooney moves that this House of Delegates endorse the two Smith-Lord bills now before the Governor for signature."

"After prolonged and disputatious debate, the question was divided. The first Smith-Lord bill was endorsed, and all other bills relating to Narcotic Drug Control, then before the Governor, were referred to the Council of the State Society for such action as might seem best. In other words, the House of Delegates failed to express an official opinion or choice, and left it a vexed and serious problem." (My report.)

I should be obliged to trust in part to memory to corroborate Dr. Rooney's statement to the effect that it was he who made the motion to refer these bills to the Council for action. My impression is that Dr. Daniel S. Dougherty suggested this disposition of the matter, obtaining the floor for the express purpose of doing so, and that Dr. Rooney took quick advantage of the suggestion and moved a substitute to the remaining part of his own motion, thus evading a vote on the second Smith-Lord bill, and referring the whole matter to the Council. The substitute motion was carried.

In his recent letter Dr. Rooney seems to deplore, and incidentally admit, that chaotic conditions exist. He proceeds until, it seems to me, he plays into the hands of his critics: "Whether or not the addict is sick, as I believe; whether as a result of his own volition or not; whether he is a criminal or a non-criminal; the same brutal treatment would not be meted out to him if instead of being addicted to narcotic drugs he had, let us say, typhoid, venereal disease—the result of his own act—diphtheria, or any of the other infectious diseases, even leprosy." And that is where Dr. Rooney makes his "big mistake." For the Fearon-Smith bill would have given us a State law to supplement and enforce the Harrison law, enabling the State to control the victim of drug addiction and compel him to avail himself of modern treatment for cure. Does Dr. Rooney object to enforced quarantine or isolation of diphtheria or leprosy? I believe Dr. Bulkley has demonstrated the comparative non-contagiousness of leprosy as seen in New York, and diphtheria has lost most of its terrors in the presence of antitoxin as a remedy, and toxin-antitoxin immunization. Still, to avoid discrimination, why not put them all, as indirectly suggested by Dr. Rooney, in the same class; but not as ambulatory cases to be treated in our offices!

Now Dr. Rooney states that in the meeting of the Council (of which I am not a member) "he suggested that the first Smith bill abolishing the Narcotic Control Commission be recommended to the Governor, and that he be requested to veto all of the other bills. In this matter the only law concerning narcotic drugs would be Federal." And "the Governor followed out to the letter the request of the Council."

So, therefore, Mr. Editor, it seems to me that on the facts which I have presented and on Dr. Rooney's admissions, I have proved that I was justified in considering him "largely responsible." Having refreshed his memory, I leave it to Dr. Rooney and those competent to judge.

J. Milton Mabbott, M.D.

19 Fifth Avenue, New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, August 4, 1921.

Tuberculosis Conference in London.—The International Union against tuberculosis held a successful three days' conference in London during the third week of July. Sir Robert Philip of Edinburgh was again the president. The keynote of the meeting was the emphasis placed upon the desirability of increasing the number of chairs of tuberculosis in the centers of medical training. The first paper read was by Sir George Newman, Chief Medical Officer of the Ministry of Health, the title of which was "State Action in the Prevention of Tuberculosis." He dealt with the history of Government action, recapitulating to the foreign delegates the various steps taken by British Governments, although he had to admit that up to the present century little or no State action had been especially directed against the disease. The first really important step was its compulsory notification act of 1908, but the true turning point in the history of the antituberculosis campaign was to be discovered in the findings of the Departmental Committee of 1912. The speaker placed the present day requirements in the treatment of tuberculosis under six heads: (1) Notification of the disease. (2) The dispensary which should be the consultation center for the neighborhood, affording clinical and laboratory facilities for arriving at an early diagnosis. Another great function of the tuberculosis dispensary is the supervision and improvement of home conditions. (3) Sanatoriums and hospitals. There should be open-air sanatorium schools, both for "the pretuberculous" and for those with definite lesions. There should be hospitals and convalescent homes for those with non-pulmonary and surgical tuberculosis. Sanatoriums should have training sections, where patients with more or less arrested disease may be "hardened up" prior to their return to industrial life. A complete scheme may in the future include industrial colonies and village settlements, though these may lie beyond State financial resources of the present time. (4) After-care work, in which is included not only the supervision, care, and if necessary, financial assistance of a patient on discharge from sanatorium, but a thorough study and a conscientious effort to put him in the best possible environment both at home and at work during the whole of his lifetime. (5) Research work. (6) Medical officers of health. It is necessary that the various public health services should be administered by, and as, one department. In practice it is often found convenient for the homes of tuberculous patients to be visited under the supervision of the tuberculosis officer, though any sanitary defects discovered are usually reported to the medical officer of health, and dealt with by him. The past seventy years in which statistical returns had become available, had witnessed a great decline of the mortality from tuberculosis among civilized people. In 1847 in England and Wales there died from phthisis, excluding acute miliary tuberculosis, 3,189 persons per million living. By 1872 that figure had fallen to 2,384, another twenty-five years reduced it to 1,356, and in 1913, the year before the European War, the figure had fallen to 961 persons per million living. There was in most countries a slight rise during the war years, but in 1920 the standard death rate from phthisis had fallen in England and Wales to 842 per million living, a decline since 1847 of 74 per cent. This considerable decline has been happening in greater or less degree in all civilized nations.

Sir Humphry Rolleston read a paper on "The Rôle of the Medical Profession in the Prevention

of Tuberculosis." He said a periodic state census of all persons should be taken so as to classify them by means of von Pirquet's test into those with open tuberculosis, those with latent infection, and those as yet free from such infection. From this should follow the segregation of the first group, not only temporarily in sanatoriums, but subsequently after passing through training colonies for long periods or permanently in partially self-supporting village industrial settlements, where remunerative work should be adapted to subnormal men. The education and disposal of the healthy children of the inhabitants of these settlements would require careful consideration. The huge undertaking of the segregation of the actively infective would, according to Professor B. Moore, at first cost from £40,000,000 to £50,000,000 annually, though falling subsequently in geometrical progression; but the advantages and eventual economy of such a scheme would vastly outweigh the initial difficulties. The two remaining groups of the population, those with latent infection and the smaller category without any tuberculous infection, should, as far as possible, be under medical observation, and particularly those with latent infection. The tuberculin method of examination would obviously be far more effective than the ordinary physical examination, with the stethoscope, the weighing machines and so forth. In the discussion that followed this paper Dr. Rist of Paris took the view that the conference might wisely resolve that the teaching of tuberculosis as a special matter should be made compulsory in all schools of medicine, Dr. Gask of St. Bartholomew's Hospital, London, held that the medical profession had failed in their duties to the nation in not insisting with all their might upon proper preventive treatment. Dr. Minor of Asheville, N. C., considered the problem a social rather than a domestic one, the problem of educating the population to a greater height of intelligence. However, he agreed that the activities of the social worker, the sanitary engineer, the educator, and the philanthropist would be useless without the cooperation of the trained physician. Early discovery was the most important factor in the prevention of tuberculosis. Professor Jonathan Meakins of Canada pleaded for the man who was the rock foundation of the medical profession, the general practioneer. He was the guide, counsellor, and friend of the community, and upon his head and hand rested the greater part of the work in controlling tuberculosis and that was in propaganda and education of the people. Lack of opportunity for healthy recreation was responsible for much. What could be expected when a man spent eight hours in work, eight hours in sleep, and the cinema filled up the remaining eight hours? Dr. Cawadais of Greece claimed that the medical men and not the politicians, should lead in organizing hygiene in general, and in the anti-tuberculosis campaign in particular. In Greece there were practitioners in hygiene as well as in therapeutics. At the close of the meeting Dr. Minor expressed the appreciation of all the visitors at the delightful welcome extended to them and the admirable arrangements made for their convenience.

During the meeting a paper of great importance was read by Professor A. Calmette of the Pasteur Institute on "Healthy Carriers of Tuberculosis." The speaker said the result of examining data as to the incidence of the disease compelled the inference that in man tuberculosis was the outcome of civilization. If the disease appeared among surroundings where no case of phthisis could be discovered, it appeared obvious that the malady was able to introduce itself only through the presence of some bacillus carrier, unknown to be so and to all seeming quite healthy, but who spread virulent germs about him from time to time. This had, to all intents and purposes, been proved, and knowledge of this unexpected danger made the organization of social defence greatly more difficult. It was patent that they must not think of forbidding suspected individuals from entering certain professions, or from traveling or living with the healthy, but they might hope through appropriate supervision and education to render them harmless. Professor Calmette pointed out that the possibility of efficiently protecting the children and the general population of countries which are still comparatively free from tuberculosis can only be contemplated on the condition of reorganizing, wherever possible, a system of detection based upon a judicious use of tuberculin tests and on clinical examination of the glandular system mainly by means of radioscopy. Sir German Sims Woodhead of Cambridge, who opened the discussion on the paper dealt with the relationship of the bovine tubercle to tuberculosis in man. It was known that geographical considerations had a great deal to do with the arguments brought forward with regard to the spread of tuberculosis. For example, in Japan, it was very evident that the human bacillus played a more important part in the process of infection than it did in such a place as Edinburgh. Whatever the popular belief might be there had been very great advances in our knowledge, not only of the distribution of tubercle, but also of the treatment. It was now possible to distinguish the bovine tubercle bacillus from the human type, and also to determine how it infected. Contrary to the view frequently held, the tubercle bacillus did much damage when it was in milk; it was often there and got there very easily. It had been proved that from 6½ to 10 per cent. of the fatal cases of tuberculosis were the result of bovine infection. Referring to the anti-waste campaign the speaker said he was afraid many of them were prone to save money in a very uneconomical manner at the expense of public health and education. Professor Leon Bernard of France suggested that as they were now in a position to consider resolutions they should send one to the British Government and other governments concerned in favor of larger supplies in the interest of public health and ultimately in the interests of public economy. Dr. Gerald Webb of the United States said that the question upon which they should be alert was that of tuberculosis carriers. In so many cases a parent before becoming a manifest consumptive had been a carrier of disease and had disseminated millions of bacilli in his immediate neigh-

borhood. Sir George McCrae said that in Scotland they considered themselves to be the pioneer nation, so far as the treatment of tuberculosis was concerned, and far ahead in that matter. They were busily engaged in combating what they believed a root of a great deal of tuberculous disease and the most formidable ally the white scourge had got and that was the question of houses. He was ashamed to say that the housing conditions were deplorable.

Progress of Medical Science.

1. Typhoid Fever Cases in Three Hospital Centers of the American Expeditionary Force. William H. Robey.
2. A Report of the Harvard Infantile Paralysis Commission on the Diagnosis of Acute Cases in 1920, with Special Reference to the Incidence of Cases without Paralysis. Francis W. Peabody.
3. Significant Reactions of the Arterial Tension. Manifestations of the Angio-Kinetic Energy, Clinically Observed and Interpreted. Claes Julius Enebuske.

1. Typhoid Fever Cases in Three Hospital Centers of the American Expeditionary Force.—William H. Robey tabulates data on 79 cases of typhoid fever, all of whom were supposed to have received three inoculations of mixed antityphoid vaccines. There were nine fatal cases in the series. Contrary to the claim made by some other writers who believe that antityphoid vaccination results in a milder course, they were unable to observe any modification in the course of their cases. While it was thought that the general symptomatic picture was sometimes obscured, there were in most cases sufficient findings to substantiate the diagnosis. The writer cannot conclude that if these patients were efficiently vaccinated their general picture differed materially from the numerous cases he has seen in civil practice during the time when typhoid fever was much more common than it now is. He concludes, however, that the value of antityphoid vaccination is beyond question, and that the need of making antityphoid vaccination universal should be impressed upon physicians who should instruct the public.

2. A Report of the Harvard Infantile Paralysis Commission on the Diagnosis of Acute Cases in 1920, with Special Reference to the Incidence of Cases without Paralysis.—Francis W. Peabody describes the work of the Harvard Infantile Paralysis Commission during a small epidemic of infantile paralysis in eastern Massachusetts which began in August, 1920. In all 133 cases were visited. Fifty-one of these were found not to have poliomyelitis. In 75 cases a diagnosis of infantile paralysis was definitely made. Lumbar puncture was performed in 54 cases. It was usually not done if the child was paralyzed and the diagnosis of poliomyelitis was clear. Special interest attaches to the cases seen in the preparalytic stage of the disease. There is nothing pathognomonic about the clinical picture before the onset of the paralysis, but there is much that is suggestive. In the preparalytic stage the most helpful diagnostic method is lumbar puncture, for in a large proportion of cases there is an increase of cells in the spinal fluid. When an epidemic of poliomyelitis is in progress the error of diagnosis based on the clinical picture and spinal fluid examination would undoubtedly be very small. A review of the therapeutic results reported since 1916 left the Harvard Infantile Commission unconvinced as to the demonstrated value of any method of treatment thus far suggested, so they collected data regarding the natural course of the disease and the frequency of the development of paralysis. In this series there were only 13 cases in which the clinical picture, the pleocytosis in the spinal fluid, and the subsequent history of the case justify the diagnosis of acute poliomyelitis in the preparalytic stage. Of these 13 only four became definitely paralyzed, while nine, or 69 per cent., did not develop paralysis. Considering the fact that the evidence at hand indicates that about 65 per cent. of patients infected by acute poliomyelitis never develop paralysis even if untreated, it is important to be extremely critical in regard to therapeutic measures. The most valuable criterion of the efficacy of treatment is a real understanding of the natural course of the disease, and it is hoped that others who come in contact with larger groups of cases will seek the same type of information.

7. Fundamental Factors in the Control of Tuberculosis, with Special Reference to the Sanatorium. Henry Boswell.

3. Puerperal Mastitis.—Franklin A. Dorman and Henry Hoagland have compiled statistics on this subject from a consecutive series of 2,000 patients delivered at the Woman's Hospital, New York. The incidence of mastitis in this series of cases was 2.8 per cent. Their patients were kept in the hospital fourteen days post partum; nine of these cases occurred after the customary date of discharge. The onset of the infection in these cases showed that from the seventh to the twelfth day was the commonest time of incidence. Mastitis should be clearly visualized as a local infection, and inflammation due to germs, and should not be confused with the lay term "caked breasts." The prophylaxis of mastitis resolves itself into prevention of trauma to breasts and nipples and elimination of contact infection as far as possible. The writers' technic in the case of damaged nipples is to use a constant dressing of either tincture of benzoin or bismuth and castor oil, from 1 dram to 1 ounce, or the lead shield, the latter being the most valuable. With a damaged nipple all nursing should be through a glass nipple shield. In cases of bleeding nursing should be temporarily discontinued. In the prevention of contact infection, the nipples are, when not in use, covered with a sterile compress or pad of gauze, 4 inches square, held in place by adhesive strips. The effect of this dressing on the patient is educational, establishing a *noli me tangere* attitude toward the nipple. The further prophylaxis involves the rapid clearing up of all infantile infections, and in case of one-sided mastitis, the prohibition of consecutive nursing from the infected side to the normal one. In the first 1,000 cases in which this particular protective dressing was not employed, the mastitis incidence was 36 cases, with five abscesses; in the last 1,000 cases, coincident with the adoption of this dressing, the mastitis incidence was 21, with three abscesses. The treatment of mastitis as soon as diagnosed is a cardinal point in success. Certain therapeutic measures seem to have almost universal acceptance, namely, the use of cathartics, the employment of a binder for pressure and support, the limitation of fluid in the diet, and the use of ice locally until the presence of suppuration is suspected. The moot points in treatment are those which involve the emptying of the breasts by massage, pumping or nursing. The writers believe that the breasts, in the absence of nipple injury, are most safely emptied by the infant, and that the continuation of nursing increases the chances of successful lactation. Massage and pumping must be most carefully employed, but may be necessary to supplement the child's nursing. When the presence of suppuration is suspected a change from cold to heat gives comfort and hastens localization. All breast manipulation should cease, including nursing. Free incision with counter drainage and irrigation with Dakin's solution will hasten recovery. In conclusion the writers urge: (1) More effort toward the prevention of contamination in the first and second weeks of the puerperium, (2) general training of the staff and nursing force, that the earliest recognition of infected breasts may be achieved; (3) prompt treatment of the infection by some rational method which will stand the test of figures showing a minimum of suppurative termination.

7. Fundamental Factors in the Control of Tuberculosis, with Special Reference to the Sanatorium.—Henry Boswell summarizes his views as regards the control of tuberculosis as follows: (1) Tuberculosis is a preventable disease. (2) A certain percentage of people are carriers of the disease. (3) The campaign for the control of tuberculosis must be one of education and not of quarantine. (4) It must extend over a long period of time and be on a big scale. (5) It must take cognizance of the fact that as the disease decreases the fight must be more carefully made, because our race becomes one of nonimmunes. (6) It will require constantly increasing sums of money, which must be secured from the public. (7) It can be secured only by keeping in touch with the people, to insure their co-operation. To do this the workers must not travel too far ahead of public sentiment, or forget public ideals. (8) No campaign can be successful unless it is a part of a general health movement and coordinated, further, with all welfare agencies and the Bureau of Animal Husbandry. (9) The educational system must include the extension department of the bureau, keeping in touch with the tuberculous population, presenting information to them in their own language, catering to their ideals, and to local and sectional peculiarities. (10) The sanatorium is the fountain head from which all this should work and through which public sentiment for the final work may be crystallized. The sanatorium is a failure so far as the prevention of the disease is concerned, unless it is operated as an educational institution rather than as a hospital. (11) A place must be had where the indigent tuberculous population may be cared for during the remaining days of their lives, in order to protect an increasingly large number of the "nonimmune" race from the dangerous carrier.

6. The Law of the Heart. E. H. Starling.

2. Lumleian Lectures on Some Points in the Etiology of Skin Diseases.—Arthur Whitefield with this number completes his course of three lectures. The first of these treated of the external causes of skin diseases, these being largely infection and irritation. In the second lecture he discussed the internal factors related in an etiological way to various forms of dermatitis, and emphasized the point that the working out of the whole physical condition of the patient had brought dermatology into a closer relationship with general medicine. Thus, the deeper insight which they had begun to gain into the true etiology of disease as it affected the skin had already in many instances been the means of securing a greater efficiency in the treatment of the patient. In the third lecture he calls attention to the fact that in the search for foci of infection the skin has received less attention than it merits. He does not find, however, that the focus of infection is always in the skin, but thinks it more often elsewhere. He has noted many cases of the most diverse eruptions which he considers to be proved to be due to chronic infective periodontitis. In some cases lupus erythematosis may be due to a chronic streptococcic poisoning, most frequently derived from the tonsils or teeth. Alluding to the influence of the nervous system on diseases of the skin, he says there is no doubt that in many instances prejudices of the observer have led to the drawing of unjustifiable conclusions, and that slip-shod clinical examination has resulted in the attributing of eruptions to the nervous system when they are plainly due to another cause. On the other hand, one cannot deal with large numbers of patients suffering from skin diseases such as urticaria, dermatitis herpetiformis, eczema, and psoriasis, in which up to the present time no specific cause is known, without being struck by the frequency with which one gets a history of mental shock or overstrain. It may be that the mental condition acts indirectly through its influence on the digestive system in causing certain skin diseases. As an instance of the relationship between the central nervous system and the skin lichen planus may be mentioned. For many years expert dermatologists have been convinced of the close relationship of lichen planus and the nervous system. Drs. Thibierge and Ravant drew off some of the cerebrospinal fluid by means of lumbar puncture. While nothing abnormal was found in the pressure or constitution of the fluid, the eruption was very favorably influenced by the procedure. The writer's experience of this method has been almost entirely favorable. In all cases so treated by him the effect on the subjective symptoms has been dramatic, and in all but two the eruption has lost its infiltrative character soon after the withdrawal. The author then discusses reflex irritation as a cause of skin disease, and expresses the opinion that there is some evidence in favor of this theory.

4. A Case of Cure of Detachable Retina.—Robert Foster Moore reports that during the last two years in the medical wards of St. Bartholomew's Hospital he has met 13 cases of detachment of the retina in patients in which it was not a complication of renal retinitis. He has admitted all such patients who were willing, and treated them on the following lines: They have been confined to bed, and 5 per cent. sodium chloride and 5 per cent. sodium citrate solutions, with the addition in each case of 4 per cent. novocaine, have been injected by means of a hypodermic syringe in amounts of about 15 minims, under Tenon's capsule over the site of the detachment. The injections cause some reaction so it is not thought advisable to repeat them oftener than about every third day. The sodium chloride is injected one day, and three days later sodium citrate; three days later sodium chloride, and so on for nine or ten injections. A man 44 years of age, with a large myopic complete crescent and a large transparent retinal detachment, was admitted on April 1 and treated on the above lines. When he was discharged on May 10 no detachment could be seen. Moore states that he does not fail to appreciate that the condition may recur, but he feels sufficiently encouraged to continue with this line of treatment in the hope that it may hold out some prospect for help in a condition looked upon as almost hopeless.

1. President's Address: Eighty-ninth Annual Meeting of the British Medical Association. On the Medical Profession: A Horizon of Hope. David Drummond.
2. A Special Address on Industrial Hygiene: Its Rise, Progress, and Opportunities. Thomas Oliver.

1. President's Address: On the Medical Profession: A Horizon of Hope.—David Drummond, addressing the eighty-ninth annual meeting of the British Medical Association, held at Newcastle-on-the-Tyne, July 19 to 23, 1921, spoke of the future of the medical profession more from the viewpoint of its efficiency in the State than from an academic and strictly scientific aspect. He discussed the question as to whether the members of the profession are satisfied with the position which the profession holds in the scheme of national polity and whether they are satisfied with themselves. The first part of this question is answered by the fact that the whole medical profession of the country is in the process of organizing itself into a vast unified guild of a medico-political kind, which later will embrace the entire world, because it has become convinced that the whole hygiene of the folk requires its utmost and careful consideration in all its aspects and because it is determined to be adequately represented in the government of the country. He points out that with the progress of medical science the people have become more discriminating than they formerly were, and that if the physician is to render full measure of service to the public he must correct certain deficiencies in himself. There are inequalities in technical attainments which render the service to the public imperfect which are dependent upon differences in education and training. These may be met by improved

methods of instruction, but the power of acquiring knowledge is not the only factor needed. The personal character of the student and future practitioner must be borne in mind as a factor responsible for inequalities in the value of services rendered. As medicine is a progressive and constantly changing art, its followers, if they are to continue efficient, must be students all their days, and this raises the important and extremely urgent problem of post-graduate education. Professor Drummond discusses the various forms that this may take, and lays stress mainly on the practitioner's self-education and on the need of verification and checking up of his work. Thus, in order to clear up any doubt as to the nature of fatal illness, necropsies should be the rule; this is very far from being the case in present-day practice. Necropsies have become less frequent in recent years than in the past, and this cannot help but have a retrograde influence. Some delay in the advance of accurate diagnosis is due to the neglect to obtain data for trustworthy statistics by postmortem examination. Furthermore, there is much waste of available statistics, and to remedy this the hospitals should be provided with officials highly trained in statistical methods and able to correlate and systematize the material now rarely utilized. Full-time professorships would further this work. Professor Drummond emphasizes the supreme importance of cultivating the faculty of observation, so as on the one hand to be able to recognize the earliest departures from health, and on the other to possess a sound acquaintance with physiological variations, and thus to assess correctly the value of abnormalities. Speaking of the present examination tests which all students of medicine must pass, he notes that there are many drawbacks. Attempts have been made to minimize these by eliminating the factor of competition and having the student "pass" rather than "class." Professor Drummond favors the recommendation made by the General Medical Council that the student be given credit for previous class and ward work as reported on by his teachers.

8. Clinically Doubtful Breast Tumors: Their Diagnosis and Treatment.—Edwin I. Bartlett agrees with Bloodgood in that the clinical studies enable one to arrive at a positive diagnosis only in cases where there are skin changes or in cases of acquired unilateral retraction of the nipple, or in cases of a lump in the breast of women under twenty-five. It is a well-known fact, however, that a large majority of breast tumors are "clinically doubtful," and the diagnosis must be arrived at by some means other than clinical studies. The only help outside of the clinical pictures comes from pathological studies, and if the diagnosis is to be made before the patient leaves the operating table, these studies must be done at the operating table. If the solution of this problem is the study of the pathology of breast lesions at the operating table, then every surgeon who operates upon the breast should be familiar with the gross and microscopic pathology or should have always at his command at the operating table a pathologist for immediate gross or frozen-section diagnosis. The study of breast tumors at the operating table is best brought about by the means of an exploratory incision. One has a choice of three proceedings: (1) Enucleation of the breast gland, (2) excision of the tumor with a narrow zone of breast tissue, and (3) exploratory cutting down onto or into the tumor before removal. The first procedure is time-consuming and divides every primary lymph-vessel from the tumor to the skin, to the axilla and to the mediastinum. It is an extremely dangerous procedure and should not be practised. The second method does not involve the division of all of the skin lymphatics, but does mean cutting across every other lymphatic from the tumor. While this method has not the objections of the first, still its objections are too numerous. The third procedure is the one advocated. It involves the radial incision directly upon the tumor, and as soon as the diagnosis is made or the necessary piece taken, the whole wound and tumor are thoroughly carbolized. After a few trials and a thorough study of each case, one can make a diagnosis from the gross appearance alone in a very high percentage of the cases. In these instances one has almost entirely avoided dissemination because the carbolic is applied immediately after the incision, with a resulting and complete coagulation. If the diagnosis cannot be determined by the gross appearance, the microscope must be employed. Summarizing, the writer states that, laying aside all other considerations and confining one's self solely to the problem of giving the greatest number of chances of cure in malignant conditions, one must take into consideration, not necessarily all, but rather a certain few clinical signs and symptoms, and one must do the complete operation or explore in every doubtful case. The exploration should be done without delay. The breast should not be removed and an interval allowed to elapse between the time of removal and the pathologist's report. One should not remove the breast or the tumor for the purpose of immediate or subsequent pathological study. One should cut down upon the tumor and should be sufficiently schooled in gross pathology to be able to make the diagnosis at a glance. Thorough coagulation with pure carbolic should be done immediately after the incision of a malignant tumor, and the complete dissection should proceed without delay. No incomplete operation for tumor of the breast should be attempted in the absence of facilities for immediate diagnosis, and the diagnosis must be confirmed in every case before the patient leaves the operating table.

9. Cultures from the Appendix.—Charles E. Farr made a study of a consecutive series of appendices, including both chronic and acute cases, but excluding all cases of perforation and of gross peritoneal infection, for the purpose of determining the bacterial content of the exterior of the appendix, and the mesoappendix, with its blood-vessels and lymphatics. It may be and probably is true that the organisms so isolated play a large rôle in the etiology of appendicitis, but the problem at hand was to determine the potential threat of the appendix to the peritoneum, its viscera, and the abdominal wall. In 131 consecutive cases the colon bacillus alone or with other organisms was found in 57 per cent. of the appendices. Of 45 acute cases the colon bacillus, alone or mixed, was present in 53 per cent. No other single bacterium appeared in any large number of cases. Eighteen appendices gave no cultural growth. The two infected wounds of 36 acute cases closed without drainage (giving 5.5 per cent. infections); each showed the colon bacillus. Of the 131 cases, 113, or 86 per cent., gave some form of growth; 122 were closed without drainage. Primary union was obtained in 117 (96 per cent.). From these observations it is concluded that the appendix is potentially an infecting agent even when the most careful technique is used. Too much care cannot be exercised in delivering and removing it. Occasional parietal and deep-seated infections will occur under the most approved technique.

2. The Diagnosis of Pernicious Anemia.—J. P. Schneider states that in general three main clinical types of pernicious anemia are met with: The anemic type in which the subjective and objective findings are hematological; the gastrointestinal type in which stomatitis, gastric symptoms, diarrheas, etc., and not seldom proctitis, are stressed in the patient's complaint, and finally the neurological, in which type subjective and later objective neurological findings are uppermost. In 107 cases tabulated by the writer on the basis of principal complaint, 62 were anemic in type, 23 gastrointestinal, and 22 cord. In the common type in which the symptoms of anemia *per se* are in the foreground (weakness, dyspnea, palpitation, vertigo, throbbing of the vessels of the neck, etc.), there is usually a sufficiently well-developed blood picture to allow of a definite diagnosis if one considers also the clinical course and bile studies. The severity of the symptoms of anemia are not in proportion to the degree of anemia, but in rather direct relation to the rapidity with which the blood is falling. In the gastrointestinal type the principal complaint is food distress. The patient may complain particularly that hot or cold or sour food or drink causes intense burning pain of the gums or tongue or both. There may be distention, nausea, vomiting, and diarrhea, one or more, and proctitis. It is in the gastrointestinal type that malignancy is often suspected. On the other hand, malignancy, particularly a bleeding, necrosing carcinoma of the *pars media* of the stomach, may be regarded as pernicious anemia. The differentiation may be made by the duodenal test. When the bleeding is enteric the normal duodenal pigments, bilirubin and urobilin, are reduced to levels comparative with the blood level. When a hemolytic process destroys blood the bleeding is parenteral and the pigment resulting must be removed through the medium of the spleen-liver complex and high values for bilirubin and urobilin with the addition of urobilinogen will be found. In the third type, the neurological, the diagnosis is more problematical because subjective symptoms alone may be present and antedate objective neurological findings as well as a positive blood picture for many months. In 80 per cent. of all cases of pernicious anemia, however, there will appear sooner or later objective findings. In a recently published study of 78 cases of pernicious anemia the pigments urobilin and urobilinogen were present in pathological amounts in all but three cases, the average total units being 3,300 units. Barring intercurrent disease, the prognosis can be somewhat evaluated by the degree of leucopenia, the platelet count, and the hematopoietic-hemolytic index. When in a given case there is present a tendency to hemorrhage, a marked leucopenia and a minus hematopoietic-hemolytic index, the evidence is overwhelmingly in favor of the disease having arrived at the stage of marrow failure.

1. Cancer and Its Treatment.—R. O. Butterfield emphasizes strongly that cancer is not merely a surgical disease; in many cases it is both a medical and surgical disease, but principally medical. After extensive study he is convinced that cancer is not a germ disease; that it is not contagious and not hereditary in the accepted meaning of the term; that it is the result of autointoxication, the local manifestation being determined by an irritation at the focus. The cancer patient is one who drinks but little water and passes but little urine. In every case in which the writer has made a urinalysis he has found a deficiency of carbonates. This rises from a deficiency of water intake and the lack of oxidation. The resulting condition is that of hyperalkalinity of the whole system. This condition may be called the precancerous stage. In this type of case all the emuctories are functioning below normal, a condition comparable with senility. In the matter of cancer treatment the hope of saving the patient lies first in an early diagnosis, teaching the laity to watch for suspicious manifestations; second, in active treatment with the object of thoroughly destroying the local growth, eliminating the poison from the system, and activating the metabolic processes. For deep-seated growths we must depend upon the knife alone or in conjunction with the electro-cautery. For the removal of superficial growths Butterworth has found Marsden's method the best. He has, however, worked out a method of injection for selected cases of superficial growths that he feels is superior to any other method. It has been successful in almost every case in which the growth could be reached by the hypodermic needle. The method is painless and can be used without a general anesthetic, whereas the plaster methods are all very painful unless an anesthetic is used. Having removed the growth, one must get the metabolic processes to functioning as perfectly as possible to avoid recurrence.

Wiener klinische Wochenschrift.

June 30, 1921, xxxiv, 26.

Treatment of Cancer of the Uterus.—Adler gives some figures of the treatment of 52 inoperable uterine cancers dating from 1913-4. Of this number 13 still live, free from relapse. As a coincidence there was a small series of 6 operable cases of which but one survives. The author used radium at a time when we knew much less about it than now, and believes that radium technic is a most difficult subject. He does not believe in a standard dose or a system of treatment. He does believe in individualizing treatment and it is most fearfully hard to know just when to stop. There is a severe alternative between giving too much radium and causing fistulæ and giving too little and stimulating some of the cancer cells to further growth. Despite statements to the contrary, there is a primary radium mortality—from sepsis (Bumm, Schaefer). He nearly lost a patient in this manner. A source of aggravation is the disappearance of so many women in the course of treatment. Some who are optimistic believe they have been cured; others have some fault to find with the treatment. Whatever is to be said of radium alone applies equally to the combination with *x*-rays. The author seems to have used the latter only since 1919, when he obtained a Reiner installation. In regard to operative cases there is no room for more radical intervention, as the Wertheim technic has been carried to the limit. The Schauta vaginal operation is suited only to part of the material and in the past ten years the primary mortality has been less than 4 per cent. Operation can go no further, and thus far radiation cannot take its place, but is indicated as after-treatment. For the present the operable case must be operated on, vaginally or abdominally, according to exact indication.

Dangers of Serotherapy in Horsemeat Consumers.—Kopaczewski warns against the use of antitoxins, serums, etc., in peoples who live on the meat and milk of the horse. These subjects, among whom are Russian Tartars, appear to have become sensitized to the action of the products of horse serum.—*La Presse Médicale.*

Book Reviews.

OPTIMISTIC MEDICINE or the Early Treatment of Simple Problems Rather Than the Late Treatment of Serious Problems. By A FORMER INSURANCE MAN. Philadelphia: F. A. Davis Company, 1921.

"THE time has come, the walrus said." Do you remember your Alice in Wonderland days when your imagination played all sorts of delightful pranks and gave such a filip to the irresponsible child life? Well, the walrus spoke the truth, but he never realized, did he, just how much his little speech could apply to the doings of a body so august as the medical profession? The time *is* ripe and the publication of Optimistic Medicine strikes one of the telling hours on the clock. Physicians have worked along, slowly gaining help here and there from allied sources, in the advancement of their knowledge of healing. Perhaps they might not acknowledge the sources of help, perhaps they might. But in the last fifteen years assistance, definite and clear, has come from one of the most capable sources in the world, one of the recognized authorities in its allied interest with medicine. Life insurance and all it means is a power for tremendous impetus toward health and longevity. Insurance progress woke up the medical profession to the value of increased health from middle life, so-called, through old age. Not only has it offered working knowledge for a healthier middle age, but in addition it points out a happier outlook for the individual as these fulfilling years are lived. The author, a former insurance man, unconsciously stamps on the reader's mind the picture of a man who has had the power and brains to study people understandingly and from a rather unique angle as they passed before him. He takes the busy physician, tells him to put on his glasses and his old smoking-jacket, sets him in front of a big open fire and talks; and as he speaks, the quiet, quizzical, humorous outlook he has gained through his intimate relationship with men and women comes into his words. He presents in this book a tolerance for human nature, its ignorance, its pitfalls, and its fine endeavors, while at the same time, and in the same kindly manner, he puts it up to his medical man by the fire.

There has been no attempt to advance any new theory of medicine, but a practical use has been made of the attitude of hope as a therapeutic measure in bringing about a normal adjustment of each individual, sick or well, toward life. One gets to detest the abused word "psychological," but it does play an important part in Optimistic Medicine, even though the term is so seldom used. There is no refuting the author's knowledge of medicine, but added to the medical viewpoint, is a knifethrust for the doctor who does not handle his patients with a big, human understanding. The chapters on The Celibate of Fifty or Sixty, Retaining Efficiency Late in Life, Mental Torture of the Body, and Getting Normal are too delightful to miss. One knows the author must have possessed at least two old-maid aunts who probably were dim shadows in his rampant boyhood. Their impression seemingly still lingers in his mind as he writes "Few people probably realize the sense of isolation which overtakes people who have gradually been left to themselves. The celibate is peculiarly liable to this fault." Again, his attitude as to what advice should be given by the family doctor to those lonely souls, the spinster—that is what he calls her—and the old bachelor, makes one unconsciously chuckle with glee, for he reads human nature with so true a focus. Imagine the single woman of today being called a spinster! Heaven save the mark! After one puts down the book comes the thought, "I knew that and that." Perhaps a resolve is made by the reader to put forth a stronger, braver endeavor to lighten the lives and to bring hope and more health to those who lean so heavily and so trustingly on the lightest word from their family physician.

THERAPEUTISCHE TECHNIK FÜR DIE ÄRZTLICHE PRAXIS. Ein Handbuch für Ärzte und Studierende. Herausgegeben von Prof. Dr. JULIUS SCHWALBE, Geh. San.-Rat. Fünfte, verbesserte und vermehrte Auflage. Price, 260 Marks. Leipzig: Georg Thieme, 1921.

THE regular biennial editions of this work were interrupted by the war so that it has now been eight years since the appearance of the fourth edition. To those who are familiar with the work it will be necessary to say only that it has been quite thoroughly revised and somewhat enlarged. There has been added a chapter on dental technique and that on gynecological technique has been rewritten. For the benefit of those who do not know the book it may be said that it consists of more than a thousand pages devoted to therapeutic technique of every variety. It is impossible to review it adequately, but nothing seems to have been omitted. There are chapters on pharmaceutics, dietetics, mechanotherapy, radiotherapy, etc., etc., and a large section of the book is given over to the more strictly surgical technique. Among the authors one will find such well-known men as Czerny, Brugsch, Boas, Zuckerkandl, Ficker and Wassermann, and by that list the value of the work may perhaps be judged. It is a reference work of some value in spite of the fact that, like most German works of this class, it will be found to contain methods that are often quite different from those followed in this country.

MANSON'S TROPICAL DISEASES; a Manual of the Diseases of Warm Climates. Edited by PHILIP H. MANSON-BAHR, D.S.O., M.A., M.D. (D.T.M. and H.) Cantab., M.R.C.P. Lond. Seventh edition, revised and enlarged, with 31 colour plates, 6 half-tone plates, 404 figures in the text, and 31 charts. New York: William Wood & Company, 1921.

IN the seventh and enlarged edition of "Manson's Tropical Diseases, edited by Philip H. Manson-Bahr, a most complete and modern study of the field of tropical medicine is authoritatively presented.

This volume is already familiar to those interested in diseases of the tropics and therefore needs no introduction; but in this edition certain important additions have been made, including the recent work of Noguchi and the discovery of the leptospira conveyed by *Stegomyia fasciata;* the researches into Rocky Mountain and typhus fever; and the Marris atropine test, possibly the most important contribution made during the war in the diagnosis of enteric fevers. The Marris test depends on the fact that a hypodermic injection of atropine sulphate, grain $\frac{1}{50}$ to $\frac{1}{30}$, is followed by a rise in pulse-rate, amounting to at least fifteen beats per minute, in health or in diseases other than typhoid and the paratyphoids; whereas in cases of enteric fever, no rise, or only a very small rise in the pulse-beat is to be noted. Marris' test is applied to inoculated patients. Here, obviously, the Widal or usual serodiagnostic detection of typhoid fever is wholly unreliable; so that the value of the atropine test, in addition to its speed and simplicity, is enhanced by the ability claimed for it to sort suspected innoculated patients into two classes, "enteric" or "not enteric."

Three unusual appendices conclude this excellent volume. The first is an appendix on medical protozoology, which is complete and mostly the work of Dobell; then an appendix on medical helminthology, entomology, etc.; and finally an appendix dealing with laboratory methods as applied to clinical medicine in the tropics. This latter section is quite complete and in every way practical. The general lucid and lucent style in which the subject matter is presented, and so characteristic of the former editions of this book, has been preserved throughout.

TUBERKULOSE-BIBLIOTHEK; BEIHEFTE ZUR ZEITSCHRIFT FÜR TUBERKULOSE. Leipzig: Johann Ambrosius Barth.

"ZUM Tuberkulose-Gesetz" is the title of the first monograph in the Tuberkulose-Bibliothek, under the editorial direction of Prof. Dr. Lydia Rabinowitsch of Berlin, a one-time American teacher at the Woman's Medical College of Philadelphia. The following are the names of the contributors: Prof. Dr. B. Möllers, Prof. Dr. M. Kirchner, Dr. O. Mugdan, Dr. Chr. Harms, and Prof. Dr. A. Schlossmann. Each of these gentlemen gives his views of what the new German tuberculosis legislation ought to be. Although the pamphlet is interesting, nothing new can be learned from it by American tuberculosis workers, since our own anti-tuberculosis laws, provisions, and sanatoria in the majority of the States of the Union are superior to anything suggested in this monograph.

Society Reports.

THE INFANT WELFARE CONFERENCE.

(From Our London Correspondent)

The second English speaking conference on infant welfare promoted by the National Association for the Prevention of Infant Mortality and the National Baby Week Council, was opened at the Central Hall, Westminster, London, on July 5 last. The meetings covered three days, the conference ending on July 7.

VISCOUNT ASTOR presided at the opening meeting and in the course of his speech said, they wanted to resolve themselves into an anti-waste conference and send out the message, "We are anti to waste of child life due to preventable causes." Public apathy was due to the fact that the victories of preventive medicine were unseen, while failures were always more prominent. This country could not afford to lose the progress gained during the past years.

DR. JANET M. CAMPBELL, senior medical officer of the Ministry of Health, in a paper dealing with "Maternity Homes" said that the ministry had now recognized between sixty and seventy homes in England and Wales, with about 700 beds, while over twenty proposals for new homes were under consideration. That was in addition to maternity beds in homes for young married mothers, and in addition to old-established maternity hospitals and poor law lying-in institutions. In spite of our modern knowledge of the causes and prevention of infection, of the successful application of this knowledge to the practice of surgery, and of the elaborate training given to medical students and nurses in surgical technic, we were, as regarded midwifery, almost back in the position at the beginning of the century before the midwives act was passed.

The Child Welfare Exhibition was opened in the afternoon of July 5, in the same building by SIR ALFRED MOND, Minister of Health, who said that of all the many subjects under the charge of the ministry there was no branch from which one derived more satisfaction, and in which were seen more results for the benefit of the country and the rising generation than maternity and infant welfare work. However great the need for economy in these days, he felt quite sure that they should not economize in this direction, and he was very pleased to see such a large and practical exhibition. There was no doubt as to the value of bringing home to people visually the methods and simple devices which assisted in the proper rearing of infants. More people sinned from ignorance than from crime, and ignorance could be removed in that way. No government department, however anxious, could produce the far-reaching results required to assist the millions of babies born every year, and it was far more important to do as they were doing by means of that exhibition to bring the mothers into close contact with practical methods and suggestions. He was a believer in voluntary effort, and it would be a pity if the experience of the war should be wasted.

Among the many interesting papers read was one by Mrs. CYRIL SMITHETT, the title of which was "Residential Provision for Mothers and Babies." She dealt with the problem of the unmarried mother and her child and said in part that during the war a great deal was heard about "war babies" and considerable fear was entertained that they would become a serious burden on the state, but as a matter of fact, the numbers were a good deal exaggerated, and taking into account the abnormal conditions of the country's life under the strain of so huge a conflict, there was really not so alarming an increase of illegitimate children as had been anticipated. However that might be there was no doubt that since the war, in the aftermath of reconstruction, and while the stormy waters of our national and individual life were still rolling restlessly, there had been a decided augmentation in the numbers of what in country villages was known as the "love child." Many and various were the reasons advanced for this state of affairs, but in the opinion of the author it was mainly due to three great factors: (a) The sudden relaxation of discipline which for the war years exercised a certain restraint on women, either in the services or in government employment. (b) The craving in every girl at the present day for pleasure; and (c) The extraordinary lack of influence on the part of the modern parent, who was apt to shirk all responsibility beyond clothing and feeding the girl. There was no doubt that in all classes the craze for amusement was tending towards immorality in its devotees, and the stories of the divorce courts showed clearly that the working girl was by no means the only sinner. Mrs. Smithett, who is the National Secretary, Reception Hostels Committee, Young Women's Christian Association of Great Britain, explained the methods by which this association aided these errant girls and their babies. The association has established homes in which they are fed and cared for while at the same time no restraint is placed upon the mothers, and when they are ready to go out again into the world, they are when necessary found work, if possible with the child. If this is not practicable, the baby is placed with a foster mother, and the girl in service as near as can be arranged, sufficient wages being insured for the mother to pay in full for the child's keep, and time off to allow of her visiting it regularly.

Another notable paper was by MISS J. HALFORD, secretary of the National League for Health, Maternity and Child Welfare. She pointed out that while it was true that Belgium and France were the first to initiate medical infant consultations, and so laid the foundations of the modern infant welfare movement, it could not be denied that it was the United Kingdom which built most rapidly and successfully on those foundations and also extended and developed the work in many more directions than had been thought of originally. Residential provision for mothers takes the form of Lying-in Homes, Convalescent Homes, and Rest Homes, both ante and post natal. It could be said at once that as yet the supply was in no way equal to the demand. More and more local authorities, however, were opening Lying-in Homes and it was obvious that these had come to stay. They were, nevertheless, expensive institutions to equip and run since they could not fail to be small hospitals, however normal might be the cases with which they mainly dealt. In the seven municipal maternity homes from which information had been received, all of which provided for an average of less than a dozen patients at a time, the nursing staff ranged from 3 to 7 and in one case there were 5 nurses and 6 midwifery pupils, and in a second there were 5 pupils to 4 nurses. The domestic staff averaged 4. The off-duty times for the nurses in most cases included 3 hours daily, half-day weekly, and one day each month or each two weeks. The domestic staff had mostly half a day weekly and additional evenings or afternoons. In only three cases was the cost per week per inmate given, and this amounted to £7, £5 4s. 6d., and £3 15s. 3d. respectively. The patients stayed two weeks in five of the homes, from 10 to 14 days in another, and an average of 19½ days at Liverpool; they paid from £1 to £2 2s. per week.

Comparing these with maternity homes run by voluntary agencies, only one of which had over 12 beds, the nursing staff with one exception was more numerous than in the municipal, and in three instances the staff, including pupils, exceeded the number of patients. The cost per head per week ranged from £1 7s. to £6 1s. 2d. Only two out of eight homes restricted the stay to 2 weeks, the others ranging from 17 days to 4 weeks. The fees charged averaged £1 10s. per week. Of convalescent and rest homes for mothers accompanied by their babies there were still lamentably few throughout the country, the National League for Health, Maternity and Child Welfare leading the way with two such homes it had already established. To be successful, they needed to be small and homelike, and experience showed that the personality of the matron was far more vital in these homes than it was in hospitals, for instance. Where, as in the case of the League's homes, only nursing mothers were admitted, the amount of help given, seeing that two were benefited at the cost of one, was very great at a low cost, a comparatively small staff only being required. In the case of many mothers their stay of two weeks in

a lying-in home was the only holiday they ever got. Even more of a real holiday was a short stay in a convalescent home, the confinement safely over, and nothing to do but enjoy to the full good fare, good care, and good air. One special difficulty with which one had to contend in running a convalescent home for mothers was that of keeping the beds filled punctually. All the arrangements might have been made satisfactorily and yet at the last minute the mother had to forego her chance of the much-needed rest because some member of her household fell ill and there was no one to replace her, or more often than not the father shirked, adding her work and responsibilities to his own even though he himself might be out of work. It was, of course, always necessary to obtain the husband's written consent for his wife to enter the home, but even so, he might at any minute come and fetch her away, if the children got on his nerves, or the household jobs got beyond him. The author showed that it cost far more to keep a baby in a Home, however economically managed, than it did in a home without a capital H. If only more of the right kind of foster-mothers were available, and adequate but comparatively inexpensive supervision in the homes were available, with regular medical inspection at the infant welfare centers, there was little doubt that they should supersede institutional care for well babies. The real home atmosphere, so essential if babies were to do well, could not be replaced even in the best of institutions; any aggregation of babies must always be dangerous owing to the risks of infection, and the cost, even allowing for that of supervision, would be decidedly less. But house shortage and consequent overcrowding in the homes was still so prevalent that it seemed impossible to hope for any immediate reduction in the number of homes for babies, many more of which under present conditions were still needed.

R. STENHOUSE WILLIAMS and J. MACKINTOSH discussed milk in its economic aspect and drew the following conclusions from investigations made by them. First, that owing chiefly to increased labor charges, the price of milk in the future must be greater than it was before the war, although not necessarily maintaining the recent high prices. Second, that if a milk of better keeping quality is desired it can only be obtained by a further addition to the costs of production. Commenting on this expression of opinion, the authors say that while it may sound lugubrious, it is questionable whether the outlook is really as gloomy as it appears to be, since there are many savings which may be effected as the result of improved methods, and these will eventually materially influence the cost to the consumer. Some of the savings which might be effected within the industry are thus epitomized: The milk producer on his part may increase the yield of milk from his herd by adopting the practice of milk recording, which will enable him to find out and dispose of his poor cows and will afford a safe basis for an economical and improved system of feeding and for the gradual improvement of his herd by breeding for higher yields of milk. The producer may also adopt more cleanly methods in the production and handling of milk and thereby lessen the loss through souring or other faults. The distributing section of the industry may contribute by taking greater care that milk, when under their control, is not deteriorated by the use of insufficiently cleansed utensils, and by handling it in such a manner that the consumer can be sure of receiving a good article.

Dr. E. W. HOPE, M.O.H., Liverpool, read a paper on the supply of milk to expectant mothers, nursing mothers and infants. He pointed out that it had now become clear that in a considerable proportion of cases by supplying the mother with milk, on easy terms, her ability to suckle the infant was restored and this principle had been largely followed. The guiding principle in this work was not the relief of destitution, but rather provision for the ailing, whether expectant mothers, nursing mothers, or infants. The extent of the work would be recognized by showing that upward of 20,000 persons were receiving milk during the year 1920, of which number approximately, and in round numbers slightly more than, 1,000 were expectant mothers, 9,000 were nursing mothers, and 6,000 were infants under 12 months of age. There were also 4,000 children between the ages of 1 year and 5 years. Approximately 325,000 gallons of fresh milk and nearly 17 tons of dried milk were distributed in Liverpool during the year 1920. The work had been in operation for approximately 15 years and had been gradually increasing in magnitude up to the year quoted. The greatly reduced infant mortality rate during the past 20 years was undoubtedly largely due to the improvement in milk distribution. It must be remembered that the work was carried on in conjunction with the Infant and Maternal Welfare clinics, and in the case of infants the mixture was prepared in conformity with the instructions of the doctor. It would be appreciated, therefore, that an immense amount of care had to be exercised in the preparation of a large number of mixtures to meet the varying ages and needs of the infants.

Dr. FREDERICK L. HOFFMAN read a paper on the influence of weather conditions on morbidity and mortality in early infancy, founded upon the results of an investigation into the sickness occurrence among infants in the cities of York and Homestead, Pa., with particular reference to the relations of weather conditions to infant diarrhea. The investigation was made jointly by the State Department of Health of Pennsylvania and the Prudential Insurance Company of America, in co-operation with the United States Weather Bureau and local health-promoting agencies. For the city of York the total number of cases considered was 1,092, while for the city of Homestead the number of cases was 1,056. These figures represented practically the entire infant population of the two communities. The purpose was primarily to determine how far environmental conditions in the broader sense might possibly be correlated as causative factors in the excessive incidence of diarrheal diseases during the summer months. It was unfortunate that for the purposes of the investigation the summer of 1920 was the mildest on record for many years. The results were exemplified by a series of tables. The first table showed infant morbidity correlated to the method of feeding. It was gathered from this table that the children who were breast-fed only, during the entire period of observation suffered a sickness rate of 2.0 per cent., whereas those who were artificially fed throughout the entire period of observation suffered a sickness rate of 13.7 per cent. Midway between the two were the children that were breast-fed and artificially fed, who suffered a sickness rate of 7.1 per cent. According to the second table, in which the results produced in children subjected to a changed method of feeding during the period of observation was noted, the children whose feeding was changed from breast to partially artificial methods suffered a sickness rate of 6.4 per cent., whereas the children who were changed from the breast-fed to the wholly artificial method of feeding suffered a sickness rate of 10.4 per cent. For Homestead the data, unfortunately, were only for the period August to October. In this investigation the results were somewhat at variance with those derived from the York investigation. But even in the Homestead figures the breast-fed children showed the lowest sickness rate, or 1.6 per cent., while the children subjected to a change of feeding during the period of observation, or from breast feeding to artificial feeding, suffered the highest rate, or 5.1 per cent. The artificially fed children suffered a sickness rate higher than the breast-fed, but the data must be considered as inconclusive. Another table indicated an excessive sickness frequency from diarrheal diseases when the maximum temperatures coincided with high minimum temperatures. Summarizing the results of the two investigations, the ratio of morbidity from all diseases was 68.7 per 1,000 infants for York and 28.4 for Homestead. For diarrheal diseases separately the rate was 58.6 per 1,000 infants for York and 16.1 per 1,000 for Homestead. The proportion of diarrheal diseases in the total morbidity was therefore 85.3 per cent. for York and 56.7 per cent. for Homestead.

Pfeifferian Septicemia.—Richardière and Laplane report the case of a child which presented the typical picture of cerebrospinal meningitis. Lumbar puncture revealed Pfeiffer's bacillus.—*La Presse Médicale.*

AMERICAN THERAPEUTIC SOCIETY.

Twenty-second Annual Meeting, Held in Washington, D. C., June 3 and 4, 1921.

(*Continued from page 350.*)

Second Day—Saturday, June 4.

The Treatment of Epileptic Manifestations in Children from the Standpoint of the Constitutional Basis.—Dr. E. BOSWORTH MACCREADY of Pittsburgh read this paper. (See page 358.)

Dr. BEVERLEY R. TUCKER of Richmond said that one hated to discuss a paper of this kind in five minutes for it contained so much of thought and suggestion that it was difficult to know where to begin or where to stop. One reason that more advance had not been made in the treatment of epilepsy was the assumption of the attitude that epilepsy was a disease. For some time he had reversed that attitude and had taken the position that convulsions were merely a symptom, just as headache or fever. With the older attitude patients usually got very poor examinations and very poor treatment, but if the state was approached from the view that the recurrent attacks were the symptom of some underlying condition, then one was compelled to make a more complete and thorough examination. Age had a great deal to do with the character of the recurrent attacks. Cases beginning in early life were due either to some constitutional inferiority handed down from ancestors or to obstetrical birth deformity. He had seen cases in which children's heads had been photographed with evidences of intracranial pressure. One child had an accumulation of cerebrospinal fluid between two of the sulci in the frontal lobe. There was no cyst wall, simply the cavity between the pia and arachnoid. The accumulation of fluid amounted to an ounce, which was evacuated and the cyst for a time was relieved; later it returned. The pituitary cases usually appeared during adolescence; in fact, he rather hesitated to make a diagnosis of pituitary epilepsy that had not occurred during adolescence. He rather agreed with Dr. MacCready that it was pluriglandular rather than simply pituitary. In fact, he doubted very much whether there was a true one-gland condition; probably all gland conditions were pluriglandular, with one gland paramountly affected. Later cases were found beginning in middle life; that was usually due to variable vascular tension while the patient was getting used to the blood pressure increase. During this period recurrent convulsions in no way distinguishable from idiopathic epilepsy occurred, and sometimes when the blood pressure became stable the attacks spontaneously ceased. This was a small group of cases. A small growing neoplasm or a small hemorrhage (sometimes a hemorrhagic diathesis) would give convulsions. Then, too, it should be realized that a convulsion was a convulsion, whether it was single, occurred in a series, or was recurrent, whether it was irregular, or whether it showed periodicity. Convulsions occurred in meningitis, brain tumor, tetanus, eclampsia, etc. These were just the same as the convulsions that occurred in a case of epilepsy. Dr. Tucker said he felt so strongly on this point that he would like to see the word epilepsy dropped altogether from medical nomenclature, for it undoubtedly stigmatized the patient, even in the toxic and traumatic cases; but if one delivered a patient and gave a cerebrocortical defect to a child, and the child had convulsions, the stigma should belong to the physician rather than to the child. He did not pretend to have solved the problem of epilepsy, but he was convinced that if the subject was approached as a symptom, whether recurrent or single, a better understanding of the subject would be gained than had been reached in the last hundred years or so.

Dr. CHARLES E. DE M. SAJOUS said that the material contributed by the Therapeutic Society was so valuable and helpful in every-day work that he hoped the time would come when it would be possible to see the volume of transactions published promptly. There was one feature of epilepsy which he wished to emphasize, for it had enabled him to help to some recoveries. He had been called one night to see a little girl whose convulsions numbered from 30 to 100 per night. She had now been well for seventeen years, although she had gone through three confinements. Recovery was due to the consideration of the intoxication originating in the intestinal canal. One should bear in mind that focal infection in epilepsy was one of its important pathogenic factors. In the study of every case he investigated every possible source of infection or toxemia, besides, as Dr. MacCready had said, any pressure symptoms or history of traumatism. The essential feature, as emphasized by Dr. Tucker, was that we were dealing with a symptom, the cause of which could sometimes be discerned and eliminated. Barium-meal and fluoroscopic determination of intestinal efficiency should be resorted to in every case. In one instance, *x*-ray examination of the abdomen revealed several calcified glands in the splanchnic area. As Dr. MacCready has also said, there was often an element of anemia in these cases, but also such usually proved to be due to the hemolysis consequent upon a focal infection. When thyroid gland was administered, one should not lose sight of the fact that it acted as a catabolizer, and that large doses favored hemolysis. Small doses should alone be given in these cases.

Dr. JACOB DINER, referring to Dr. Sajous' remarks in regard to the earlier publication of the Transactions, said that the action of the Society in increasing the dues would facilitate that end. At the same time, it should be remembered that the papers and the discussions usually appeared within a few months and were available in the MEDICAL RECORD. If they did not appear before that time it was because the papers were not in the hands of the editor, and an effort had been made to obviate that. If there were such a thing as adopting a slogan for each meeting on bringing out the literature for the meetings, the last meeting and this one would furnish excellent material. At the last meeting, emphasis had been placed on the importance of treating the patient and not the disease; and if he had to choose a slogan for this meeting he would choose: Seek the cause and not the symptom. This point had been ably brought out by Dr. MacCready and by Dr. Tucker in the discussion, whereas it was often lost sight of by the practitioner. Certain diseases had been named instead of naming certain symptoms; and these symptom-complexes had been applied to the diseases so named, instead of regarding them merely as symptom-complexes possibly present in many pathological conditions. If this meeting would do nothing more—it had done much more—than calling the attention of the physician to the necessity of following the French slogan that underlying all manifestations of trouble they should *chercher la femme*, we should have the slogan: *Cherchez la cause*.

Dr. GEORGE H. HOXIE of Kansas City inquired in regard to the prognosis of the epilepsy due to pituitary disturbance. In his own work the treatment by the administration of pituitary extract had been very unsatisfactory and he could not see any permanent benefit from it. He questioned the etiology of the disorder as being anything more than a cortical irritation from causes as varied as the number of the cases.

Dr. MACCREADY requested that Dr. Tucker answer Dr. Hoxie's question, as he had had more experience in that direction.

Dr. TUCKER replied that if pituitary treatment was applied to all cases of epilepsy that occurred during adolescence the results would be discouraging; but if the cases were carefully selected, with clinical and radiographic evidence and treatment applied on the first appearance of convulsions during the period of adolescence, as he had indicated the previous day, good results might be expected. Out of 17 cases reported in 1919, 4 at that time had not had convulsions for over 3 years; he selected these cases, thinking it was fairer than the more recent cases. Now, 9 cases had had no attacks for over 3 years and 4 of these had had no convulsions for from 6 to 9 years; two had had pituitary gland substance irregularly. If they took it regularly they would not have attacks; if they dropped it, the attacks would recur. So far as he could estimate, these 17 cases represented only about 8 per cent of the cases that came to the office in ordinary private practice. The group was small and depended on the selection of cases. One case had been lost track of; another

one had been included in the second group, but the patient was found to have three brothers and sisters in an institution, so it was taken out of the adolescent group. He repeated that if the cases were selected one could expect results.

Acromegalia with Leucemia.—Dr. HYMAN I. GOLDSTEIN of Camden, N. J., presented this paper, which consisted of a comprehensive review of the literature of the subject and a report of a case. This patient, a male, 43 years of age, had been under his observation for ten years, since 1911, at which time he was apparently in good health except for very slight disturbance of vision and occasional headache. His family and past history were unimportant. His history during the next few years was more or less that of progressing acromegaly. A study of the blood as early as 1915 and 1916 showed a nearly normal picture, except that the white blood cells showed a distinct tendency to increase up to 20,000, though the differential count was apparently normal in all respects. In 1918 the blood picture had changed considerably. The blood examinations then showed red blood cells 3,750,000, white blood cells 26,000, hemoglobin 78 per cent. The differential count at this time showed a marked reduction in polymorphonuclears to 35 per cent, and a distinct increase in small lymphocytes to over 50 per cent. For an uncomplicated acromegaly this was an unusual blood picture. The question came up whether this was the beginning of the leucemia, without evidence of lymphomegaly and splenomegaly. During the past ten or twelve months there had been marked changes in the blood picture, with a white blood count varying from 80,000 to 115,000 and a lymphocyte percentage of 90 to 97. The huge spleen and the lymphomegaly now left no room for doubt that this was a case of leucemia in an acromegalic. Whether this was more than a coincidence the writer was unprepared to say. The unusual features of the case were the absence of pressure symptoms though the *x*-rays showed a much enlarged sella turcica; loss of sexual power for a period of six years or more, followed recently for the past two and one-half years, by a return of all sexual power; the occurrence of lymphatic leucemia, with splenomegaly and lymphomegaly for the past sixteen months. The writer had found no other case of acromegaly recorded in the literature, associated with leucemia, and such a large sella turcica and without ocular disturbances, or any pathological changes in the eye grounds, and a normal basal metabolic rate. Following *x*-ray treatment there was improvement in the bones, spleen, lymph glands, and pituitary.

Dr. WILLIAM F. MILROY of Omaha, Neb., referred to a case of acromegaly which occurred in his experience, probably twenty or more years ago. The woman was under observation for about a year but he did not now recall the whole duration of the symptoms. The woman was 35 or 40 years of age. She developed to an extreme degree all of the hypertrophies characteristic of the disease, and suffered from glycosuria. Finally her tongue became so greatly enlarged that her mouth could not contain it. This enlargement was hypertrophic, not inflammatory. Gradually her mouth was forced continuously wide open and she became unable to take or swallow food and died from inanition on this account. This occurred before the *x*-ray was available for diagnosis. The autopsy showed the anterior lobe of the pituitary body, almost spherical in form and enlarged to some six or eight times its normal size. Apparently there was no involvement of the posterior lobe. The sella turcica was completely flattened out. No report was ever obtained from the pathologist who made the autopsy of the microscopic findings. The speaker had hesitated to refer to this case because of the incompleteness of the report, but did so at the request of Dr. Goldstein and because one saw but few of these patients die as a direct result of the disease, the case going to autopsy.

Disease as Seen Through Therapeutics.—Dr. M. LEVEN of Paris presented this paper as a contribution from the French Therapeutic Society. The paper was read by Dr. Sajous. (See page 360.)

Dr. SAJOUS said he had been impressed by what the writer had said in regard to purgatives, and thought that a knowledge of endocrinology would indicate the importance of avoiding excessive purgation in conditions of the intestinal canal, and all purgatives, perhaps, before operations were instituted. Purgation swept from the intestinal canal a product named "secretin" by Starling, which not only served to liberate and activate pancreatic enzymes, but also to promote the production of succus entericus. Normally, the temporary deficiency of the physiological activators of intestinal functions, shown by temporary constipation, slight lassitude, etc., readjusted itself. If, however, during this period an abdominal operation was performed, it found the alimentary tract, including the pancreas and liver, functionally deficient. Moreover, Dr. Sajous's researches had shown that, besides these functions, the intestinal enzymes contributed to the succus entericus active bactericidal and antitoxic properties which did much, working in conjunction with the bile, to prevent autointoxication. Hence many of the evil effects credited by an increasing number of surgeons to preoperative purgation.

(To be continued.)

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held May 11, 1921.

THE PRESIDENT, DR. GEORGE M. PIERSOL, IN THE CHAIR.

THE program of the evening was The Treatment of Summer Diarrheas.

Differentiation for the Purpose of Treatment.—Dr. J. CLAXTON GITTINGS read this paper, stating that summer diarrhea might be considered as occurring in two main types, one due primarily to infection of the intestinal wall and the other due to a disorder involving the intestinal contents. The distinguishing feature of type I was that bacteria, usually introduced in food or drink or by contact with infected articles, invaded the wall of the gut and set up definite anatomical changes. Type II might be viewed as a functional disturbance rather than a somatic disease, since the basic disorder involved the intestinal contents rather than the intestinal walls. Infectious diarrhea had two chief symptoms, ileocolitis and dysentery. Although hot weather, and especially the combination of heat, humidity, and stagnant air, undoubtedly predisposed to any of the diarrheal diseases, the infectious form was seen occasionally in cool weather. Presumably the infecting organisms invaded the wall of the gut early, causing infiltration of the mucosa. In severe types the inflammation spread to the submucous layer and involved the solitary lymphatic nodules. The latter might break down and ulcerate, resulting in small punched out cavities. Since the disease was a systemic as well as a local infection we usually found parenchymatous degeneration to a greater or less extent in liver, kidneys, and spleen. The intestinal lesions in the functional form of diarrhea showed a wide variation in intensity, but the chief change consisted in a superficial catarrhal inflammation. It would seem that this was due, for the most part, to the irritation of abnormal or excessive products of fermentation. The onset in both types was sudden, at least during the hot weather. Toxemia would be present in both types, depending upon the severity. As a rule, however, the patient with functional diarrhea would show a higher initial temperature and more severe toxic symptoms than were seen in ileocolitis. Prostration at first depended upon the severity of the toxemia and of the diarrhea and vomiting. It was apt to be more severe at first in the cases of functional diarrhea. Later it was equally well marked in the infectious type. In functional diarrhea flatulence and foul odor to the stools were early symptoms, but the number of stools soon tended to diminish and blood was seldom seen. Abdominal pain occurred at first, but was not a symptom of major importance. In ileocolitis the stools consisted in large part of mucus, and the odor might not be especially offensive. Frequency was marked and persistent, blood was a characteristic finding, while abdominal pain and rectal tenesmus were present in a majority of cases. Cholera infantum, a form of functional diarrhea, usually was given a separate place because of its special characteristics. As a rule it occurred in babies who had been suffering from chronic intestinal disor-

ders. The first symptoms were prostration and fever, soon followed by severe and protracted vomiting and a profuse watery diarrhea. The stools were as frequent as in the worst cases of ileocolitis, but, after the initial emptying of the gut, consisted of serous transudate rather than mucus. The reaction was acid at first, but soon became alkaline. Tenesmus was rarely seen, and, as the disease progressed, the fluid ran from the bowel without any control by the sphincter. The abdomen was shrunken. Tenderness and rigidity of the abdomen were lacking. In such cases dehydration of the tissues occurred early and became extreme and the loss of weight was shockingly rapid. The urine was scant, highly acid, and usually showed albumin. Death occurred in stupor, often within 48 hours of the onset. Because of the excessive loss of fluid from the bowel and the absence of any signs or symptoms of a severe inflammation or congestion of the intestinal mucosa, it would seem that cholera infantum might be a form of general toxemia rather than a specific affection of the intestinal tract.

The Water Treatment in Diarrhea.—Dr. JOHN D. DONNELLY read this paper, saying that one of the complications of gastroenteritis, when accompanied by vomiting and severe or prolonged diarrhea, was dehydration. This was the result of a rapid loss of water from the body, causing a depletion of fluid in the circulation and in the tissues which brought about a concentration of the blood. Concentration of the blood produced a diminished blood volume, increased its viscosity, diminished its rate of flow, which in turn led to an accumulation of toxins and waste products, passive congestion of the kidneys, oliguria, diminished oxidizing power of the body cells, and favored breaking down of body tissues. This state of dehydration called for immediate replenishment of water in the infant's body. In the absence of vomiting, if the dehydration was only slight, water by mouth usually sufficed—four to ten ounces daily between feedings, according to the age. If this method was not practical, water might be introduced by a nasal tube into the stomach. This offered advantages in that it was painless and devoid of danger or of unpleasant after-effects, with possible exception of irritation of the nares. This could be obviated by the instillation of liquid petrolatum into the nose before the introduction of the tube and the use of white vaseline as a lubricant on the tube itself. Once dehydration was definitely established and in the presence of severe or prolonged diarrhea and vomiting, recourse must be had to introducing fluid into the infant by means other than by way of the mouth. Four routes were offered: by rectum, subcutaneously, intravenously, and intraperitoneally. Rectal intolerance usually was established so early that the enteroclysis became not only useless but actually harmful. Hypodermoclysis of sterile physiological saline solution might be used in threatened dehydration or in those cases where dehydration was slight; 5 or 6 per cent. glucose solution might likewise be used. This procedure was somewhat painful and the amounts which could be injected into small infants fell short of the needs of the average case of moderate or severe dehydration. Intravenous administration of fluid had obvious advantages. In the Children's Hospital they had used sterile solutions of normal saline, 5 per cent. sodium bicarbonate, 5 per cent. glucose, and a glucose-acacia solution made up with glucose 5 gm., acacia 10 gm., normal saline 100 c.c. The practical difficulties of entering the infant's veins and the danger of the introduction of large amounts of fluid by the longitudinal sinus had made them reserve this method for the treatment of marked dehydration cases only where the call for replenishment of the depleted vascular system was an urgent one. The use of the intraperitoneal route for the introduction of fluid was a comparatively recent therapeutic measure. They had avoided the intraperitoneal injections in all cases where there was any abdominal distention as the possibility of penetrating the intestinal wall under such circumstances could not be denied. There was no local irritant action when the solutions employed were isotonic; otherwise abdominal distention, signs of local discomfort and peritoneal irritation would follow. Following the introduction of fluid in dehydrated infants their general appearance became better, fontanelles more full, pallor lessened, they tended to be quiet, their facial and body evidences of dehydration disappeared, vitality increased, the pulse showed signs of increased volume and tension, toxicity was lessened, and urine secretion increased.

Dietetic Management of Summer Diarrheas.—Dr. WILLIAM N. BRADLEY read this paper, in which he said that summer diarrheas were so distinctly and definitely preventable that it seemed advisable to consider for a moment the dietetic prophylaxis of the subject before proceeding to the management of the pathological condition. One needed only to call to mind the oft-repeated statement that six bottle-fed babies died to every one that was breast-fed, to realize the tremendous immunity to disease which the breast-fed infant possessed, and particularly was this true with reference to diarrheas. That a very large percentage of women could and would, with a little encouragement and advice, nurse their babies was proved by recent statistics of the prenatal department of the Starr Center. If early weaning should become necessary, it should always be avoided in the summer months if possible. At the first sign of disturbance the stomach and intestines should be immediately cleansed of all irritating substances by a laxative or colonic irrigation or both if necessary; all food should be withheld for a period varying from six to forty-eight hours, being replaced by boiled water, cereal decoctions, or saccharine tea, etc. According to the bacteriologic etiology of the summer diarrheas, two types were distinguishable, namely, the fermentative and the infectious. Both types might bear a distinct relation to bacteria. In the former the bacteria, being chiefly saprophytes, did not seriously injure the tissues and in the latter chiefly parasites which directly or indirectly injured the intestinal walls. Both types might be present and the distinction became an artificial one. The fermentative or typical summer diarrhea was characterized by intoxication or infection, or both. It was due to preponderance in the intestine of one form of bacteria, usually saprophytic, either acid-forming or putrefactive. If the former type of bacteria were in excess, then the carbohydrate and fat elements in the food must be reduced or entirely withdrawn for a time. If the putrefactive were found to be in excess, then the protein element must be withheld. By far the greater number of diarrheas was caused by the excess of the former, the acid-forming bacteria. The stools of this form of diarrhea were loose, green, acid and irritating, and might contain mucus. The relief of the condition and the restoration of the digestive functions lay in suitable dietary management. The infectious type of summer diarrhea known as ileocolitis was distinguished by inflammation. It was frequently difficult to draw a sharp distinction between these two types. In both there were toxic substances resulting from bacterial growth causing symptoms and in some cases pathologic changes. In infectious diarrhea the bacteria principally concerned were the dysentery bacillus, the gas bacillus, colon bacillus and streptococcus. The stools of this type, alkaline in reaction, showed increasing frequency, with the presence of blood and mucus and finally pus. Membrane might be present in the severer cases. Diarrhea caused by the first, or dysenteric group should be fed largely on carbohydrates. Lactose solution was probably the best form because of the development of lactic acid which had an inhibitory effect upon the gas bacillus. This should be given in a 5-7 per cent. solution, either alone or with barley water. As the acute symptoms subsided, thickened cereal gruels, fresh beef juice and broth thickened with meat fiber might be substituted for the weaker decoctions. In particular he would suggest the use of flour ball with either the cereal or broth diluent or in the form of brown flour soup, using one or two teaspoonfuls with each feeding. Here again the return to any form of milk food should be begun with caution and abandoned at the first sign of relapse. Diarrheas related to the second group of organisms, the gas and allied bacilli, should be treated by feeding a moderately high protein, the carbohydrates being kept low, and by introducing acid-forming bacteria into the diet. Either skimmed milk, buttermilk, or caseon milk might be used, starting with a weak formula and increasing according to the progress of the patient, as indicated

by the stools. Fat should be kept low. Convalescence would be slow, covering a period of from six to eight weeks or longer with frequent tendency to relapse.

The Abuse and Use of Drugs.—Dr. JOHN F. SINCLAIR read this paper, saying that the drugs which had been most grossly misused were undoubtedly the laxatives, especially castor oil and calomel. These were of undoubted value when properly employed in appropriate doses, as an initial laxative, at the very beginning of a gastrointestinal attack, but, when they were administered again and again, they unnecessarily depleted the system of the water and mineral salts in which it stood greatly in need and weakened rather than supported the bodily defenses. Furthermore, in those cases which were first seen late in the attack after gastrointestinal disturbances had progressed beyond the acute stage it was frequently ill-advised to administer either castor oil, calomel, or other laxative, for the reason that the baby could not survive if the reserves of water and salts were still further and rapidly depleted. In the case of castor oil it was also true that it tended to produce vomiting and that large or frequently repeated doses might cause sufficient irritation of the intestinal mucosa to bring about the appearance of blood in the stool quite apart from any inflammatory condition which might then or subsequently exist. Next to the laxatives the greatest misuse or abuse of a drug was in connection with the administration of opium. On the one hand the laity and certain physicians pressed the use of opium, usually in the form of paregoric, to such limits that it was not infrequent in hospitals having infant wards to receive patients who were suffering from unmistakable opium poisoning. Probably, however, the more frequent error made was in withholding opium entirely when a proper dosage would allay excessive peristalsis and relieve pain. Where the symptoms and signs pointed to an irritation rather than to an inflammation of the intestinal tract the procedure was simple. A prompt and energetic use of castor oil or calomel followed by calcined magnesia or milk of magnesia was indicated, and this medication should be followed by a period of temporary starvation. In the acute inflammatory or infectious types preliminary use of castor oil or calomel followed by magnesia was indicated and should precede brief periods of starvation as had been described above. If these cases did not promptly show an abatement of the diarrhea, and especially if there was evidence of excessive peristalsis and pain, opium in the form of camphorated tincture was indicated. In the more severe and active forms of the inflammatory types under consideration it was not unusual to meet with varying degrees of acidosis brought about by the dehydration and loss of mineral salts previously referred to. To anticipate and prevent any such eventuality it was a wisely established practice to administer sodium bicarbonate in 15 grain doses every three hours routinely to all infants who were more than very mildly ill with inflammatory or infectious forms of gastrointestinal disease. Should this prophylactic measure not be successful in warding off acidosis, as was sometimes the case, one must give larger doses by mouth or administer it either intravenously or subcutaneously. The urine must be made alkaline and must be kept so.

Dr. ARTHUR NEWLIN said that it seemed to him, from a purely clinical view, that, if one left aside the question of bacteriological examination of the stools the difference between the fermentative and the infectious form was merely a question of degree. The child with an infectious diarrhea would show changes in the walls of the alimentary canal. We frequently saw cases in which the child would start with what was apparently a fermentative diarrhea, which shortly afterward became infectious with blood and mucus in the stools. As far as the clinical aspects of the case were concerned, it was difficult, and practically impossible, to make two separate entities of the types. He did not think that we could lay down the law that the thing to do was to evacuate the bowel and then put the child on some sort of nonirritating diet. The treatment varied with the articles that the experience of the practitioner had found to be satisfactory. The usual method was to give a laxative, either castor oil or a saline. He believed that in the earlier stages a saline was better than the oil and more efficacious. Small doses of Epsom salt acted as a sedative to the stomach and insured a thorough evacuation of the bowels within twenty-four to forty-eight hours. One of the dangers was to starve the children too long and keep them on either salines or oil, thus weakening their resistance. Once in a great while a case of vomiting, with small, infrequent stools, was mistaken for a simple case of infectious diarrhea, whereas a more careful examination of the abdomen would have shown it to be a case of intussusception or appendicitis. Very often pyelitis was accompanied by diarrhea and the pyelitis was overlooked. He thought that very frequently we were fooled into thinking that the child was better, in one of these forms, especially the dysenteric form of gastroenteritis, by finding a few stools that showed marked improvement without there having been any change in the diet.

Dr. A. GRAEME MITCHELL said that in spite of work done on the study of this subject, these summer diarrheas continued to take their toll in infant deaths. It was not possible to treat these cases routinely as a group. When it came to the dietetic management, it was quite necessary to differentiate the types. It was not always possible to do this, but certain clinical points helped. The type of stool helped us to differentiate between the fermentative and the infectious type. For the dietetic treatment it was necessary to know whether the organisms were acid-forming or protein splitting organisms. That could usually be told clinically by the reaction of the stool. If it was found highly acid, the chances were that acid-forming organisms were at fault. In that case the dietetic work was pretty definite. Remembering that organisms of that type thrived on carbohydrate, it would be wrong to give carbohydrate percentages in the food. If the protein-splitting organisms were at fault, the reaction of the stool would be alkaline; and one must not give protein food, because it encouraged their growth. The water treatment, which Dr. Donnelly had taken up so well, was, of course, the treatment to be used in all types, if dehydration were present. The peritoneal route was supplanting all others, because more fluid could be given, because it was a life-saving procedure, and because administration by the sinus was not the fool-proof procedure that the intraperitoneal administration was.

Dr. JAMES H. MCKEE said that the main thing in these summer diarrheas was expressed by Dr. Bradley, when he spoke of them as being mostly preventable. He thought, in the first place, that we needed a great big arousing of the sociological conscience. We talked a great deal about the things that might be done in communities to prevent these summer diarrheas; but, after all, the old Scriptural saying, "By their fruits ye shall know them," should be applied here. We had not playgrounds; we had not recreation centers; we had not the adequate instruction on the subject of clothing; we had not the places where the children might be taken when the temperature of the rooms was such that we knew that the children were "fried all day, and parboiled all night," which was what practically happened. We all knew the effect of external temperatures upon these affections. With regard to the question of food, then, Dr. Bradley expressed the thought that so many more mothers might nurse their babies; but half a loaf was better than no bread at all, and, if they could not nurse their babies fully and adequately at the present day, the complementary feeding was the thing to resort to, and not the supplemental feeding.

Dr. HARRY LOWENBURG said that one thing that Dr. Gittings did not emphasize sufficiently was the etiological influence of food. He rather seemed to stress the importance of external heat. His own feeling was that food was the determining etiological factor, whether we were dealing with a carbohydrate or a fat disturbance, or with a protein disturbance. If we regarded the situation in this light, we had a working basis for therapy; but if we insisted on external temperature as being of too great importance, it did not enlighten us as far as treatment went. About laxatives, his own personal experience had led him to decide carefully whether or not the patient needed one. He never used calomel, because it was too slow and too irritating.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Colorado State Board of Medical Examiners.

Denver, January 4, 1921.

(Concluded from page 307.)

PATHOLOGY.

1. Differentiate atelectasis and bronchiectasis.
2. What is the commonest cause of bleeding from the nose, excepting bleeding the result of trauma?
3. What is the usual location of apoplectic hemorrhage of the brain? What underlying pathological condition of the blood vessels predisposes to such hemorrhage?
4. Which heart valve is most commonly attacked in acute endocarditis? What lesions of the valve may result from such infection?
5. What pathological condition of the heart is accompanied by ascites without edema of the extremities?
6. Name two common complications of lobar pneumonia.
7. What is the Schick test and what is its significance?
8. In what location does the tubercle bacillus most frequently attack bone?
9. What pathological changes in the urinary tract result from prostatic hypertrophy?
10. An unmarried woman of 33 consults her physician on account of a tumor of the right breast of 6 years duration; size of the tumor is uninfluenced by menstruation. There has never been associated pain nor discharge from the nipple. There has been no loss of weight. On examination the right breast is half again as large as the left. Along the outer margin of the right pectoralis major is an evident mass about 8 cm. long, 5 cm. broad, and 2 cm. thick. On palpation the tumor is flattened in front and behind, has sharply defined margins, is adherent neither to the skin nor the underlying tissues, and apparently has no connection with the breast, the gravity causes it to ride downwards and overlie the breast margin. No glands can be felt in the axilla. What is the probable nature of the tumor? Is it malignant or benign? *The patient has active tuberculosis.*

OBSTETRICS.

1. Name four varieties of placenta prævia. (*b*) State your plan briefly how you would care for this type of hemorrhage in childbirth; especially your technique from the very first of your treatment.
2. State your manner of handling (*a*) the 3rd stage of labor (normal). (*b*) Give your technique and indications for the manual detachment of the placenta.
3. What manner of treatment do you advise and use for a post-partum hemorrhage?
4. Give the symptoms gained in a careful examination of a transverse position in labor.
5. How would you care for a transverse position after labor has been fully started?
6. Differentiate blue asphyxia and white asphyxia in the new-born.
7. What treatment do you use in resuscitating the white asphyxia?
8. Give the clinical symptoms of an extrauterine pregnancy.
9. Give your technique in the management of a normal L. O. A. labor in the 2nd stage.
10. Make a diagram of a normal pelvis given in centimeters or inches showing 4 lines of measurements.

SURGERY.

1. Discuss diseases of the salivary glands.
2. Discuss tumors of the posterior triangle of the neck.
3. Give signs, symptoms and diagnosis of (*a*) parietal lobe, (*b*) cerebellum (tumors).
4. The acute abdomen: Give differential diagnosis.
5. Pyelitis: Give differential diagnosis.
6. Describe fractures about the elbow.
7. Describe dislocations of the hip. Give differential diagnosis.
8. Describe Pott's fracture and Colles' fracture.
9. Describe the varieties of flat foot and give the causes.
10. Female middle aged, fell from a porch, distance of 4 feet. The scalp was lacerated over the left parietal region; no loss of consciousness. She was unable to move her legs. Patellar reflexes were abolished. There was analgesia below the navel. She could not pass the urine. She gave a history of typhoid, lues, and pneumonia. Discuss the case.

ANSWERS.

PATHOLOGY.

1. *Atelectasis* is a condition in which the lungs have not been expanded, and the walls of the airspaces lie together.

Bronchiectasis consists of dilatations in the bronchi.

2. The *commonest cause of bleeding from the nose* (next to trauma) is plethora, or ulcers, or infectious diseases.

3. The *usual location of apoplectic hemorrhage*, is in the corpora striata and optic thalami; the lenticulostriate and lenticulo-optic branches of the middle cerebral artery are most frequently involved. Vascular degeneration, arteriosclerosis, and atheroma are the main pathological conditions of the bloodvessels which predispose to such hemorrhage.

4. Mitral regurgitation is the most common valvular lesion.

5. Ascites, without edema of the extremities, is met with in tricuspid regurgitation.

6. Two common complications of lobar pneumonia:—Pleurisy, and empyema.

7. *The Schick test* is a test used to ascertain if a person's blood or tissues contains a sufficient amount of antitoxin to protect him from contracting diphtheria. If there is none, or too little antitoxin, insufficient for protection from diphtheria, a positive reaction occurs within one or two days. The test is used to find out what persons are liable to take diphtheria if exposed and also to ascertain what persons should be allowed to look after diphtheria patients. Those who give positive reactions should receive immunizing doses of diphtheria antitoxin.

8. Distribution of Tuberculous Bone Lesions. *Cranial Bones.*—Rarely become carious with an external abscess.

Vertebræ.—Affected with central osteomyelitis or superficial caries.

Ribs.—Periostitis with abscess.

Long Bones.—Epiphyses, caseation, necrosis, osteomyelitis, or chronic abscess—this is much the commonest situation. Diaphyses rarely are the seat of periostitis, osteomyelitis, or chronic abscess.

Pelvis.—Near the sacro-iliac joint or any of the epiphyses, e.g., the crest of the ilium.

Carpal, Tarsal, and Phalangeal Bones.—Commonly affected by osteomyelitis, necrosis, or caries. The os calcis, astragalus, scaphoid, or one phalanx, may be separately diseased, but usually more than one bone or joint are affected. (Groves's *Synopsis of Surgery.*)

9. *Enlargement of the Prostate* "is a condition commonly found in patients over fifty years of age, which interferes with the act of micturition, and may destroy life by setting up secondary changes in the bladder and kidneys, like those produced by urethral stricture. Little is known as to the causation. There may be general enlargement of all the tissues of the prostate, or it may consist of a number of masses which look like adenomata. Fibromyomata are said occasionally to be present. The changes induced are—(1) the prostatic sheath of pelvic fascia is thickened; (2) the close connection between the capsule and the sheath is loosened, so that it is easy to enucleate the gland; (3) as the gland enlarges it projects upwards between the mucous membrane and the sphincter vesicæ, so that an intravesical enlargement is seen. This may be a collar-like projection, looking like the cervix uteri, or, if one lateral lobe only projects into the bladder it takes the form of what used to be called the 'middle lobe.' (4) The prostatic urethra is lengthened, and may be laterally compressed or distorted, and the intravesical prominence may be a hindrance to the passage of an ordinary

catheter; (5) the bladder is hypertrophied from the excessive work thrown upon it, and may become fasciculated and pouched. In the pouch, which lies behind an intravesical enlargement, residual urine collects, and, if cystitis comes on, phosphatic stones may be formed there." (*Aids to Surgery.*)

10. The tumor may be a lipoma (benign); or it may be a myoma (benign); or it may be a tuberculous tumor. It is strange that with the active tuberculosis there has been no loss of weight.

OBSTETRICS.

1. *Four varieties of placenta prævia:*—(1) *Complete or Central*, when the placenta completely covers the internal os. (2) *Incomplete*, when it does not completely cover the internal os. (3) *Partial*, when it overlaps the internal os. (4) *Marginal*, when it just reaches the internal os.

Treatment of placenta prævia, at term: (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation turn the child and make the breech engage in the os; or, if the head presents forceps may be used if speedy delivery is necessary. The strength of the woman is then the main point to be cared for, and if in a reasonable time the uterus seems to be incompetent, the child may be delivered by art. In some cases of central placenta prævia, where rapid delivery is required, cesarean section may give good results for mother and child. (Landis' *Obstetrics.*)

2. In the *third stage of labor* the physician should seize the fundus of the uterus through the abdominal wall and knead and rub it until it contracts vigorously; then he should press it down in the direction of the axis of the pelvic inlet. This should last for about a quarter of an hour after the child is born. The placenta, after it is expressed, should be carefully taken by the physician so as to be sure that it is *all* expelled; at the same time care must be taken that no particle of membrane remains behind. Fluidextract of ergot may be administered. The *dangers* are: hemorrhage, retained placenta or clots or pieces of the membrane, and sepsis.

Treatment of adherent placenta: "A finger—one or two—must be insinuated between the uterus and placenta at some point already partially separated, or, if no partial separation exists, at a point where the placental border is thick, and then passed to and fro transversely through the uteroplacental junction, acting like a sort of blunt paper knife, until separation be complete. Another mode is to find or make a margin of separation as before, and then peel up the placenta with the finger-ends, rolling the separated portion toward the palm of the hand upon the surface of the still adherent part. Great care is necessary to avoid peeling up an oblique layer of uterine muscular fiber, which might split deeper and deeper until leading the finger-ends through the uterine wall into the peritoneal cavity. Should such a splitting begin, leave it alone and recommence the separation at some other point on the placental margin. It is sometimes only possible to get the placenta away in pieces. These should be afterward put together and examined to indicate what remnants are left behind. It may be quite impracticable to get out every bit, but small remnants or thin layers too firmly adherent for removal do not distend the womb enough to create hemorrhage from their bulk, and the subsequent danger of septicemia from their decomposition may be obviated by injecting warm (2 per cent.) creolin water into the uterus twice daily until everything has come away." (King's *Obstetrics.*)

3. *Treatment of Postpartum Hemorrhage.*—Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin, or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

"In the presence of actual hemorrhage the treatment varies according as the placenta is still within the uterus or has already been expelled. In the former case the uterus should at once be grasped through the abdominal wall and firmly kneaded. If firm contractions come on, all is well, but if the hemorrhage continues and the uterus relaxes as soon as the kneading is stopped, the placenta should be expressed by Credé's method; and if this cannot be accomplished and the patient's condition is alarming, manual removal may become necessary. . . . If the hemorrhage does not cease after the delivery of the placenta, the cause should be ascertained and suitable treatment instituted. Tears should be located and their edges brought together by sutures. On the other hand, if the hemorrhage is the result of the retention of placental tissue, the carefully disinfected hand should be carried up into the uterus in order to seek for and remove the retained cotyledon. Under such circumstances the hand acts as a most efficient irritator, causing the uterus to contract energetically. After separating the retained portion of the placenta the hand should not be withdrawn at once, but should be allowed to recede gradually as it is forced down by the contraction of the fundus. If the hemorrhage is due to atony, the uterus should be vigorously kneaded, and from forty to sixty minims of ergot or of ergotol administered hypodermically. . . . If these measures are not attended with the desired result, a very hot intrauterine douche of several liters of sterile salt solution should be employed. . . . If the hemorrhage persists in spite of the douche, our only hope of controlling it is by packing the uterus tightly with sterile gauze. Before resorting to the use of the pack it is always advisable to palpate the interior of the uterus, as occasionally a portion of the placenta may have been retained, even though immediately after expulsion the organ may have apparently been entire."—(Williams' *Obstetrics.*)

4. TRANSVERSE POSITION. "*Abdominal Signs.*—The abdomen is unusually wide from side to side, while the fundus frequently does not rise above the umbilicus. Both fetal poles are absent from the excavation after labor is established. A third sign is the presence of the head in one of the other iliac fossa, and a fourth is presence of the breech on the opposite side.

"*Vaginal Signs.*—There is glove-finger protrusion of the bag of waters; the presenting part is smaller, more yielding, and less distinctly rounded than the hard globular head. *Especially significant is absence of any presenting part at the onset of labor.* After labor is well established the presenting part is a small, rounded prominence; it is distinguished from an ischial tuberosity by the absence of a companion; from it run the humerus, the clavicle, and the spine of the scapula in radiating lines. The neck is felt on one side of the presenting part, the "grid-iron" sensation afforded by the ribs on the other; the axilla can be made out; the elbow is identified by the olecranon; the position is determined by the location of the scapula to the right or left, anteriorly or posteriorly. The axilla and the elbow look toward the feet; the thumb points toward the head. When an arm is prolapsed the hand is to be distinguished from the foot, and the right from the left hand. On shaking hands with the fetus, the right hand of the examiner fits the right hand of the fetus, and *vice versa.*"—(Polak's *Manual of Obstetrics.*)

5. *Management of transverse position after labor has started:*—"The membranes should be preserved; to secure full cervical dilatation the bladder and rectum must be evacuated; the capacity of the pelvis, the size of the child, the relative position of the head and the dorsum, the situation of the retraction ring, and the degree of thinning of the lower uterine segment are all to be noted. When the cervix is fully dilated version should be performed, cephalic or podalic, by the bipolar or the internal method, followed by immediate extraction under anesthesia. *If the membranes have ruptured*, the degree of cervical dilatation, the condition of the uterus, of the patient, and of the fetus, determine the treatment. If the cervix is only partially dilated, and the child is alive and freely movable within the uterus, bipolar podalic version should be tried, a foot brought down and allowed to dilate the cervix before the extraction is completed. If the condition is complicated with prolapse of the cord, the cervix should be dilated manually or split, and an immediate

internal podalic version and extraction made. Reduction of the malpresentation is often possible, even in the presence of a spastic uterus, with the aid of the genupectoral or the Trendelenburg position and deep anesthesia. In impacted and irreducible shoulder presentation decapitation will be required. Cesarean section should be considered as a possible alternative when the child is alive and the uterus has not been infected."—(Polak's *Manual of Obstetrics.*)

6. In asphyxia of the newborn, the child either does not breathe at all, or only very feebly. There are two forms: (1) *Asphyxia livida*, in which the child is cyanotic; the face and skin generally are of a dusky purple hue, the conjunctivæ are injected, and the eyes protrude. The cord pulsations are generally slow and full. (2) *Asphyxia pallida*, in which the child is pale and generally relaxed; the surface is cold and the appearance anemic.

7. *Methods of resuscitation of an asphyxiated infant at birth.*—In every case, foreign matter must be removed from the air passages; then any of the following may be tried: (1) *Holden's method* of direct insufflation with oxygen. (2) The use of the *pulmotor.* (3) *Direct* (mouth to mouth) *Insufflation.* (4) *Schultze's Method*—For inspiration the child should be suspended by the shoulders, face from the operator, by placing an index finger in each axilla, holding the thumb in front and two fingers extended over the posterior aspect of each shoulder, expanding the chest, while the head is kept steadied and extended between the ulnar surfaces of the hands. For expiration the position is inverted by swinging the trunk and lower limbs upward and toward the operator's face, flexing the body in the lumbar region. *The first movement should be one of expiration*, which helps to rid the trachea of mucus. The objections to this method are, first, the chilling of the body; second, the shock involved, so that in feeble infants, if used at all, it must be done with great caution. This, and direct insufflation with oxygen, or by mouth to mouth, are the most effectual methods in asphyxia of the newborn. (5) *Sylvester's Method.*—The child is placed in a supine position, with the head well extended by a fold of blanket under its neck. For inspiration, the arms are drawn well above the head; for expiration, they are placed by the sides and the thorax gently compressed. The value of this method is increased by making forward traction on the tongue during inspiratory movement. (6) *Byrd's Method.*—The child is held supine upon the hands of the operator at right angles to the forearms. For inspiration the radial borders of the hands are lowered. For expiration they are raised. The child is successively folded and unfolded. (7) *Laborde's Method.*—With the child lying in a supine position on a table, or in a warm bath, with the head extended, gentle intermittent traction is made on the tongue about eighteen times to the minute. (8) When respiratory movements have been established *but remain persistently feeble*, a weak Faradic current, one pole of which is applied to the nuchal region and the other over the epigastrium, combined with the continued inhalation of oxygen, may induce deeper and stronger respiratory efforts. (9) Should all of the foregoing methods fail, and the fetal heart, however slow, continue to beat, an injection into the umbilical vein of 30-50 cm. of sterile normal salt solution, containing 0.5 per cent. of fructosate of sodium, may be given. The salt solution dissolves CO_2.—(From Polak's *Manual of Obstetrics.*)

8. *Extrauterine pregnancy* is a pregnancy in which the ovum is developed outside of the uterine cavity.

"When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The *os uteri* is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*"—(*American Text-book of Obstetrics.*)

9. *During the second stage of labor*, examinations should be made only when necessary. In multiparæ the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.—(*Pocket Cyclopedia.*)

10. The diameters and measurements of the female pelvis are easily remembered from the following table:

	Antero-posterior	Oblique	Transverse
Brim	4 inches	4½ inches	5 inches
Mid-plane	4½ inches	4½ inches	4½ inches
Outlet	5 inches	4½ inches	4 inches

In external pelvimetry four measurements are generally taken: (1) between the anterior superior spines of the ilium, normally about ten and a quarter inches; (2) between the external edges of the iliac crests, normally about eleven inches; (3) between the heads of the two great trochanters, normally about twelve and a quarter inches; and (4) between the spinous process of the last lumbar vertebra and the upper margin of the anterior surface of the symphysis pubis, normally about eight inches.

SURGERY.

1. DISEASES OF THE SALIVARY GLANDS.—*Inflammation of the Parotid Gland.*—1. *Epidemic Parotitis*, or mumps, is highly infectious, and is marked by fever, swelling of the parotid, and socia parotidis.

2. *Simple Parotitis* may be due to injury or calculus in the duct, and is marked by pain and swelling.

3. *Suppurative Parotitis* may occur in pyemia, and in scarlet or typhoid fever by extension along Stenson's duct. The gland becomes swollen and tender, the skin over it tense and edematous, and the pain severe. The pus is apt to burrow deeply in the neck owing to the density of the overlying fascia, so that, unless opened early, toxemia, and even pyemia, may ensue.

Obstruction of salivary ducts results from cicatricial contraction or the presence of salivary calculi. The gland rapidly enlarges when stimulated by eating; the swelling subsides afterwards as the saliva slowly gets past the obstruction. When a calculus is present there may be an offensive discharge. Complete blockage may produce a cyst, which bursts and causes a salivary fistula. Calculi are commonest in the sub-maxillary and sublingual ducts.

Tumors of the parotid gland may be mixed (consisting of cartilage, fibrous tissue, myomatous tissue, and structures resembling gland tissue), or malignant (carcoma, carcinoma, or epithelioma).

Salivary fistula arises from injuries dividing Stenson's duct. Much inconvenience is caused by saliva running over the cheek. If the buccal portion is involved, the duct should be slit up within the mouth; but if the fistula is in the masseteric portion, a tube

must be passed from the buccal opening to the opening on the cheek, and retained there for some time, gradually shortening it as the canal becomes re-established. —(From *Aids to Surgery.*)

2. *Tumors that may be found in the posterior triangle of the neck*, are: Lipoma (the commonest), fibroma, enlarged lymph glands, tuberculous glands, osteoma; Hodgkin's disease, bronchial cysts, and cystic hygroma.

3. *Tumors of the Parietal Lobe.* "Tumors of this lobe can be recognized by the presence of attacks of Jacksonian epilepsy preceded by sensory symptoms, and later by the presence of a marked loss of muscle sense or astereocognosy. If situated in the lower part of the parietal lobe, they may produce word-blindness and often agraphia."

Tumors of the Cerebellum. "Tumors of the cerebellum, in addition to producing the well-marked symptoms of increased intracranial pressure, produce somewhat characteristic focal symptoms. Vomiting is quite frequent. Early optic neuritis with blindness occurs very early, and paralysis of the external rectus muscle is very common and often bilateral. There is also apt to be rigidity of the neck, and involvement of the olfactory, oculomotor, and trigeminal nerves on the side of the tumor. One of the most characteristic symptoms is a severe occipital headache, most marked upon arising. Attacks of amyasthenia and general vertigo are also frequent. Another characteristic symptom is the so-called cerebellar ataxia. This latter is especially marked in children, who have a tendency to fall to one side in walking; usually toward that upon which the tumor is situated."—(Eisendrath's *Surgical Diagnosis.*)

4. *Acute abdomen* may be due to violent injury, ruptured ulcer of stomach or duodenum, acute pancreatitis, suppurative cholecystitis, appendicitis, ruptured appendix, acute intestinal obstruction.

Symptoms common to all these conditions are abdominal rigidity, severe pain, fever, shock, anxious expression, cold, clammy extremities, cold sweats, nausea and sometimes vomiting.

In case of *ulcer* there will be history of recurrent dyspepsia, hunger pain, sour eructations, hematemesis, and blood in stools. Tenderness is most marked in or near the epigastric region in the midline.

In *pancreatitis*, there will be symptoms of intestinal obstruction, nausea, vomiting (progressively bilious, feculent, and fecal), constipation; on auscultation of abdomen there will be complete absence of sounds of peristaltic movement.

In *cholecystitis*, there is a possible history of typhoid, the patient has a palpable gall bladder; there are tenderness and rigidity over gall bladder; sometimes fever.

Appendicitis will show tenderness over McBurney's point, rigidity of right rectus muscle.

Obstruction shows hyperperistalsis, gurgling, spasmodic pain definitely referred to one point.

5. *Differential Diagnosis.* "Pyelitis is to be distinguished from perinephritis abscess, cystic kidney, tuberculosis of the suprarenal body, and impaction of the colon. The accompanying table may serve, in a measure, to differentiate these conditions, which are distinguished only with extreme difficulty.

PYELITIS.	NEW-GROWTHS OF THE SUPRARENAL BODY.	TYPHLITIS WITH IMPACTION OF THE COLON.	PERINEPHRITIC ABSCESS.
1. History of renal calculi common.	1. Tuberculous diathesis.	1. History of obstinate constipation which has existed for a long time.	1. History of renal colic the rule. Traumatism to the region of the kidney.
2. Pain and tenderness in the region of the kidney. In extreme cases the pain becomes tearing or boring in character. Pain continuous, and may rarely be localized in the bladder.	2. Pain, boring in character, and located at the tenth rib on the right and at the eleventh on the left.	2. Some pain and tenderness along the ascending colon.	2. Pain quite general, and limited to one or other loin.
3. Temperature 100° to 103° F., and is usually of the hectic type.	3. Temperature normal.	3. Temperature normal or but slightly elevated.	3. Temperature of the hectic type with morning remissions and evening exacerbations. Fluctuates between normal or subnormal, and 102° to 104° F.
4. Contour of the loin not distorted.	4. Often slight fullness posterior and below the twelfth rib.	4. Contour of the loin distorted, and there may be bulging of the abdomen over the impacted colon.	4. Distortion of the normal contour of the loin.
5. In uncomplicated pyelitis the kidney is not palpable.	5. Hard tumor palpable above kidney.	5. A soft, dough-like tumor which is readily outlined.	5. It is usually possible to palpate a mass in the region of the kidney.
6. Urine contains pus, albumin, mucus, and at times blood. Large casts covered with bacteria are occasional findings.	6. Urine normal.	6. Urine contains a large amount of indican.	
7. Blood may show evidences of secondary anemia, with a moderate increase in the number of leukocytes.	7. Secondary anemia, leukocytes normal.	7. No leukocytosis.	7. A decided leukocytosis develops early, and continues throughout the disease.
8. *x*-Ray may reveal the presence of calculi in the renal pelvis.	8. *x*-Ray negative.	8. *x*-Ray negative.	8. *x*-Ray negative.
9. Catheterization of the ureter of the affected side recovers urine containing pus.	9. No pus in urine.	9. No pus in urine.	9. No pus unless kidney tissue is involved.

(Anders and Boston's *Medical Diagnosis.*)

6. "In examining an injury to the elbow, the injured side should be compared with the uninjured. The two condyles and the tip of the olecranon should receive first attention. During extension they form one line; during flexion they form a triangle of which the apex or olecranon is toward the hand. The head of the radius should be felt just below the external condyle. When the arm is flexed to a right angle, a ruler placed along the back of the arm does not touch the olecranon. The forearm is naturally in a position of slight abduction relatively to the arm.

"*Supracondyloid fracture* resembles backward dislocation of the radius and ulna, but (1) the relative positions of the bony points are unaltered; (2) the arm is shortened; (3) the projecting end of the upper fragment is felt above the crease of the elbow; (4) the deformity is reduced with crepitus, but readily reappears. If there is much swelling, it is impossible, without a skiagram, to come to a proper conclusion. Sometimes the lower fragment is displaced forward.

"*T-shaped fracture* is the result of direct violence, and consists of a transverse supracondyloid with a vertical fracture running into the joint and separating the condyles. The condyles are widened, and can be moved on each other; great swelling comes on rapidly.

"The *condyles* may be broken by direct violence. Fracture of the external always involves the elbow joint. Abnormal mobility and crepitus distinguish fracture of the condyles. Fracture of the internal condyle may or may not involve the joint.

"The *olecranon* is usually broken by direct, sometimes by muscular, violence. If separation is complete, the upper fragment is drawn up; if the fibrous expansion of the triceps is untorn, there is no displacement. The base of the olecranon is the usual site of the fracture. There is inability to extend the forearm, and effusion of blood into and around the joint quickly follows.

"The *head of the radius* is broken by direct violence or in connection with dislocation. Separation of the epiphysis occurs in children. If the head is completely detached, it does not move with rotation of the lower fragment, and crepitus is felt."—(*Aids to Surgery.*)

7. HIP JOINT DISLOCATIONS.—*Varieties—Backward:* (1) On to the dorsum ilii; (2) on to the sciatic notch. *Forward:* (3) on to the obturator foramen; (4) on to the pubis.

Dorsal dislocation: Head of femur lies on the dorsum ilii, and can be felt in the buttock. The obturator internus is ruptured in most cases. The short rotator muscles are lacerated. The trochanter lies well above Nelaton's line and approximated to the anterior superior iliac spine. The leg is shortened two to three inches. The iliotibial band is relaxed. The leg is flexed, adducted, and inverted. The femur crosses the lower third of the opposite thigh. The toe rests on the opposite instep. A hollow exists in Scarpa's triangle.

Sciatic dislocation: Similar to the above, except in the following:—The obturator internus tendon is intact and lies over the neck of the femur, holding it down in the sciatic notch. Shortening amounts only to one inch or less. The axis of the femur crosses the opposite knee. The great toe rests on the dorsum of the opposite great toe.

Obturator dislocation: The head of the bone lies on the obturator externus in the obturator foramen. The abductor muscles are lacerated. The trochanter is obscured, the iliotibial band is tense. The leg is lengthened, the toes point forward and outward. Flexion, abduction, and rotation outward are well marked. The head of the femur is felt in the perineum. The capsule is torn in its lower part. Pain refererd to the distribution of the obturator nerve.

Pubic dislocation: Similar to the above except: The femoral head is felt under Poupart's ligament. The leg is shortened about one inch. Abduction and eversion are more marked, the toes pointing outward.—(Groves' *Synopsis of Surgery.*)

8. *Pott's* fracture is very common, and is due to indirect violence, such as turning over on the inside of the foot. The strain tears through the internal lateral ligament of the ankle or tears off the tip of the malleolus: then the astragalus is pressed against the inner side of the external malleolus by the continuation of the violence. The fibula is overbent, and breaks about three inches above the tip of the malleolus. At the same time the foot is displaced outward or outward and backward. In many cases, however, the displacement is slight.

Treatment.—"An anesthetic should always be given, and the fracture reduced by relaxing the calf muscles and applying traction to the foot. The limb must then be fixed on the back splint, with side splints in addition. The foot must be at right angles to the leg, the bony points in line, and the posterior displacement corrected. The surest way of maintaining the foot in good position is to at once apply plaster of Paris. Other splints used are Dupuytren's and Syme's horshoe splint. Massage and passive movement at the end of ten days are advisable, the fragments being firmly grasped to prevent displacement."—(*Aids to Surgery.*)

Colles' fracture is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downwards from behind. The lower fragment is driven backwards and upwards, and rotated to the radial side, carrying the hand with it into the position of abduction, and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, viz.: (1) the hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture. *Treatment:* Disimpaction and reduction are brought about by grasping the hand by the "shaking-hands" grip, extending and adducing the hand and lower fragment. The arm is then fixed on a splint. It is very important in this fracture to start massage and passive movement not later than the end of the first week to prevent stiffness. Union is firm in three weeks.—(*Aids to Surgery.*)

9. FLAT FOOT in a simple form consists in a mere loss or flattening of the arches of the foot, but it is nearly always combined with some degree of valgus, *i.e.* of abduction and eversion of the front part of the foot.

Causes: Static Conditions, i.e. long standing in growing persons.

Congenital Conditions: very long feet.

Paralytic: Paralysis of the tibials and extensor muscles.

Inflammatory: Rheumatic or gonorrheal affections of the foot rapidly soften the ligaments, and the arches of the foot give way.

Traumatic: After Pott's fracture, or severe sprains or injuries of the ankle, there is a great tendency for flat-foot to be left.—(Groves' *Synopsis of Surgery.*)

10. The case, as reported, suggests (1) *Hysteria;* but (2) the woman may have had *locomotor ataxia;* what is the condition of the pupils, Romberg's symptom? or (3) she may have sustained *fracture or dislocation of a vertebra* in the upper lumbar region; what did the back show? An *x*-ray of the spinal column would be of service; (4) she may have had a *previous myelitis,* or *hemorrhage* into the spinal cord. Information is needed on several points; is there complete anesthesia?

Cerebral Rheumatism.—Marchand and Mignot report an alleged case of this affection. The patient, a man with rheumatic and alcoholic antecedents, developed suddenly a crisis of acute articular rheumatism, the treatment of which was limited to compresses of salicylic acid. On the third day of the attack cerebral symptoms set in—mental confusion and violent agitation—which made it advisable to intern him. By this time the joint symptoms had receded. On the day after internment death took place in coma. The entire duration of the crisis was six days. Autopsy showed an intense congestion of the meninges and cerebrum, with profound changes in the pyramidal cells, but there was in inflammation. The liver was the seat of fatty degeneration. Such a condition as cerebral rheumatism is recognized, and consists of a subacute meningoencephalic intoxication occurring in the predisposed subject, who is usually an alcoholic.—*La Press Médicale.*

Miscellany.

NEW BOOKS AND OLD.

XII. SOME NEW BOOKS

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

Papers and Addresses by William H. Welch.—From the Johns Hopkins press come three ponderous tomes containing the papers and addresses of Dr. Welch, whose name is known from one end of the world to the other as Professor of Pathology of the Johns Hopkins Medical School and as the talented advisor of practically all of the great medical projects developed in this country. Anyone who knows Welch, knows what an indefatigable laborer he is, but it is not until one views the bibliography as printed in the third volume that one really realizes what a tremendous worker and writer he has been. From the year 1875, in which he wrote his graduation thesis, to 1921, his contributions number four hundred and eleven.

The first volume contains his contributions to pathology and preventive medicine. These writings are preceded by a delightful introduction by Simon Flexner, who gives a biographical sketch of Welch which will be read with great interest. Of particular import is the account of his student life abroad and the great masters of medicine who were his teachers.

The second volume contains his bacteriological studies and his contributions to the various systems of medicine and surgery. One of the most interesting of these is his paper on the treatment of diphtheria by antitoxin, which was the subject of an address opening a discussion on this subject before the Association of American Physicians in Washington, 1895. His clearness of statement and his air of authority had much to do with the prompt introduction of diphtheria antitoxin into the practice of medicine in this country.

I find, however, that the third volume, containing as it does his contributions on medical education and medical history and biography, is much better reading. One of the most readable of these papers is an address delivered at the Massachusetts General Hospital on the sixty-second anniversary of Ether Day, October 16, 1908. This is entitled, "A Consideration of the Introduction of Surgical Anesthesia," and for a short study, is one of the best that has been done upon this subject. He quotes from the Elizabethan dramatist, Middleton, who makes a character in one of his plays say,

> I'll imitate the pities of old surgeons
> To this lost limb, who, ere they show their art,
> Cast one asleep; then cut the diseased part.

Welch goes on to state that, "we know that none of the procedures, and 'not poppy, nor mandragora, nor all the drowsy syrups of the world' were safe, effective, and available agents to benumb the senses during a surgical operation." He also calls attention to the remarkable fact that objections have been raised against the use of chloroform to relieve the pain in childbirth, and tells how Sir James Simpson quoted from a letter of a clergyman who declared that chloroform is "a decoy of Satan, apparently offering itself to bless woman, but in the end it will harden society and rob God of the deep earnest cries which arise in time of trouble for help." To this Welch adds, "if this clergyman remembered the primal curse, he forgot the earliest example of anesthesia when, in the resection of a rib for the creation of Eve, 'the Lord God caused a deep sleep to fall upon Adam.'"

Another paper well worth reading is the "Relation of Yale to Medicine." In this and in his remarks before the students of Yale, at Changsha, Hunan, in China, he pays a splendid tribute to Yale, for, being a Yale man, Welch can seldom resist extolling the virtues of his Alma Mater. One finds, too, a reference to an almost unknown physician, who was as well a clergyman and poet, Michael Wigglesworth, one of whose works was entitled "God's Controversy with New England, written at the time of the great drought, Anno 1662." One trusts that he was a better physician than poet. This is a sample:

> New England where for many yeers
> You scarcely heard a cough,
> And where Physicians had no work,
> Now finds them work enough.

Of great importance too are some of the biographies, especially of some of the masters of medicine that he knew well—Rudolf Virchow, John Shaw Billings, Silas Weir Mitchell, and of some who lived before as—Nathan Smith and Francis Donaldson.

I cannot close without commenting on another short paper entitled "The Times of Vesalius. Contributions of Vesalius other than Anatomical," which, while it contains nothing new, enables one to see clearly how the lesser lives were overshadowed by the three great sixteenth century giants, Vesalius, Paracelsus, and Ambroise Paré.

Every medical library should have these volumes containing the writings of Welch on its shelves.

Reminiscences of a Student's Life at Edinburgh in the Seventies.—This little book has the faint touch of pathos in it, which always accompanies returns of older men to the haunts of their youth. It is written under the pen name of Alisma (George Skelton Stephenson). It is a small affair, easily tucked in a pocket and can be read during a spare half hour. It starts in a curious way about the calyx of the wild rose about which there was a riddle in Latin which Professor F. M. Caird has translated delightfully. This riddle had its origin in a certain peculiarity in the calyx of the wild rose, in which two of the sepals are bearded, two are not, and one is bearded on one side.

> Quinque sumus fratres, unus barbatus et alter
> Imberbisque duo, sum semiberbis ego.

Translation.

> Five brothers take their stand
> Born to the same command;
> Two darkly bearded frown,
> Two without beards are known,
> And one sustains with equal pride
> His sad appendage on one side.

This riddle of the rose is of a great antiquity and has been commented on considerably by various writers.

The reminiscences in which there are delightful little accounts of people and places known to the author is illustrated with numerous portraits of fa-

mous Scotchmen of the period. Alisma was in the University at the time of the admission of women into the medical school which followed the dogged perseverance of Miss Sophia Jex-Blake. The entrance of women resulted in a very considerable disturbance, even going as far as riots and mobbing of the little band of six or seven young ladies who were courageous enough to start on the career of medicine.

One of the teachers referred to with great affection is Mr. Joseph Bell, one of the Extramural lecturers. He had remarkable powers of observation and deduction and it was he who inspired Sir Conan Doyle to conceive the character Sherlock Holmes. He also mentions John Hughes Bennett who had a moral antipathy to the new fangled name "Physiology." Bennett introduced cod-liver oil in the treatment of tuberculosis, of which plague he himself was an early victim. His life was marked by a controversy with Rokitansky, of Vienna, over the pathology of leukemia which Bennett called "leucocythæmia." Alisma goes on to state that he saw the famous Rokitansky only once, and that at the unveiling of a statue in the Vienna hospital grounds. This must have been in the good old days when the "perfect patient" at the *Allgemeine Krankenhaus* was said to be one who would have his diagnosis made by Skoda and the autopsy by Rokitansky.

The author closes with another visit to Edinburgh when he says that he felt very much like Rip Van Winkle and made all haste he could to get away.

Dr. C. W. G. Rohrer, of Baltimore, a bibliophile with a library that at once causes envy, has furnished me with a letter from Dr. Stephenson. Dr. Rohrer, by the way, is now printing in the *Medical Pickwick* a series of articles on the medical poets entitled "Medical Men and the Muses."

Dr. Stephenson says:

> I appreciate very highly your praise and the evident delight my little book has given you. The book was only written for such as your good self; it has given rise to many such letters as yours and has been most generously reviewed by all of its reviewers. I wrote it during the leisure of the last week of March, 1918, and I have since wished I had been a little more careful in its general construction.

These little reminiscences are well worth reading even though they are much tinged with that sweetly sad melancholy that always attends such writings and which is so akin to the sadly sweet melancholy of the romantic writings of youth.

Margaret Fuller.—Katherine Anthony has recently written what she calls a psychological biography of Margaret Fuller. It has the great merit of being brief and is exceedingly easy reading, while at the same time it gives one a very vivid picture of a very curious personality. Anyone interested in Freud's theories and the psychology of dreams will find much in the volume to their liking.

Margaret was a precocious child, over-educated by her father, given to describing her sensations and her dreams and making many statements that might have been written to-day by what Miss Anthony calls "those profoundly irritating Freudians." For example, "The passions are not unfrequently felt in their full shock, if not in their intensity, at eight or nine years old." This appeared in a book review written in 1846.

Margaret Fuller grew into a remarkable woman. One of her first experiments in feminism were the famous "Conversations" which she held in Boston from 1839 to 1844. She was a remarkable talker and a prolific writer. In 1844 she published her "Woman in the Nineteenth Century." As Miss Anthony states, "The only predecessor of Margaret's book was Mary Wollstonecraft's 'Vindication of the Rights of Woman,' published fifty years before." For two years she was editor in chief of the *Dial*, which was chiefly the expression of the personalities of Margaret Fuller and Emerson. In the first number she had an essay on critics in which she makes the following statement:

> The critic is beneath the maker, but is his needed friend. The critic is not a base caviler, but the younger brother of genius. Next to invention is the power of interpreting invention; next to beauty the power of appreciating beauty, and of making others appreciate it; for the universe is a scale of infinite gradation, and below the very highest, every step is explanation down to the lowest. . . . Nature is the literature and art of the divine mind; human literature and art the criticism on that; and they too, find their criticism within their own sphere.

She once made a trip to what was then the Far West and she describes an overnight stop at Ross's Grove, of which she says, "We ladies were to sleep in the bar-room, from which its drinking visitors could be ejected only at a late hour. . . . We had also rather hard couches, mine was the supper table." The experience of her Western trip appeared in a little volume entitled "Summer on the Great Lakes." It was read by Horace Greeley and through Mrs. Greeley, Margaret went on the staff of the *Tribune* as a critic. She later made a trip to Europe where she met Carlyle and many other notables, among them the Italian revolutionist Mazzini. She continued her travels to Paris where she met George Sand, and then to Italy where she lived a more or less exciting period of her life, enlivened by a love affair with an Italian nobleman by the name of Ossoli. Her baby was born in 1848, shortly after which she returned to Rome and soon after married Ossoli.

The revolution having failed, Margaret decided to return to America. She had misgivings both as to the safety of the voyage and as to her reception in New York society after her Fourieristic adventure. Perhaps fortunately, she did not have to experience what would doubtless have been her fate at the hands of her New York acquaintances. The sailing vessel on which she, her husband, and her child were passengers, went ashore, just outside of New York and the entire family, refusing to trust themselves on planks to the mercy of the waves, were drowned.

Miss Anthony's book is well worth perusal. The relations of the remarkable Margaret Fuller to society in general and to such men as Emerson, Carlyle and Hawthorne, make interesting reading.

The Passing of the "Plus Ultra."—With the beginning of the new year there passed out of existence an interesting medical journal, *Plus Ultra*, published in Madrid by Joaquin Nuñez. This rather remarkable publication lasted three years, then the high cost of publication forced the publisher to notify the subscribers that the journal would be stopped, and the collaborators passed to *Los Progresos de la Clinica*.

Plus Ultra was somewhat a departure in the European medical publishing in that it attempted to bring out a large journal, printed on a fine quality of paper, elaborately illustrated not only in the usual black and white cuts, but also in colored plates of a high degree of excellence. A considerable amount of attention was paid to contemporary biography, and a certain number of illustrated articles appeared on the subject of medical history. For the main part the articles were of a more or less practical nature, dealing with medical and surgical conditions. There was also a rather good review of the progress of medicine in other countries, and a considerable number of pages were devoted to book reviews, rather more comprehensive than is usually the case; these appeared under the head of *Crónica Bibliográfica*. The journal was marred by what was probably an inevitable introduction of advertising pages, printed in colors, in the midst of the reading matter. These, however, were inserted so as to permit of their being removed before the numbers were bound.

One regrets that such a valiant attempt at superior medical journalism failed so soon.

Napoleon and Medicine.—Several articles with this caption are appearing on the editorial pages of *La Presse Médicale*. In the issue of June 18, 1921, xxix, 48, it is stated that Napoleon, the superman, did everything to invite disease. He worked like a plough ox, turned night into day, ate rapidly of indigestible food, was under emotional stress daily, and indulged in sexual pleasures immoderately, yet was hardly ever ill in his life of ailments brought on himself. He suffered in his time from scabies, malaria, grippe, and twice from stomach crises of which nothing is known. These attacks occurred at the time of severe reverses and we are left in doubt as to whether the gastric crisis was responsible for the military non-success, or vice-versa. Incidentally we learn that the failure of the Russian campaign is now attributed to the attack of influenza which overtook him at Moscow but the author doubtless means that the attack was disastrous through the morbidity of the army rather than the chief. As far as he himself was concerned he owed little to the medical profession. It is said that Napoleon dominated every one with whom he came into contact, with few exceptions. Of six who defied him to his face three were medical men—Desgenettes, Percy, and Larrey. The conflicts arose over the care of the wounded. Once when Napoleon accused some of those wounded in the thumbs of self-mutilation Larrey withstood him to the finish. But aside from these men who clashed with the Chief on individual occasions there was Corvisart, his personal physician, who was doubtless privileged to speak plainly, who antagonized the Emperor continuously. At the outset of his career an obscure surgeon-major, Bienvelot was of service in showing the future Emperor how disease could cripple an army—malaria for example, contracted by ignoring the lessons of experience. It is said that Napoleon never forgot the teachings of this early associate.

The Medical Bibliophile Society.—Doctors have passed as book-lovers from time immemorial. In order to test the truth or falsehood of this adage, there assembled on the evening of May 30, 1921, at the professorial headquarters of the Medical Faculty and under the presidency of Dean Roger, some thirty physicians, for the purpose of forming a society to be known as the Bibliophile Physicians. This number is of course only a starter, which is certain to increase apace, because of the large number of book-lovers among medical men. The idea does not stop with a mere rendezvous for book collectors, but for a much wider circle of book-lovers in the most general sense. It is not necessary to love a book that it be printed on vellum and curiously bound, for the society will welcome good books in any disguise, and especially at the present time of substitute bookmaking. If the books be daintily printed and bound so much the better of course. The main thing at present is the substance and not the form, but the ambition of the future is to secure *de luxe* editions, which will be reserved for members of the society. The grand idea is this, that the better the book the better should be its dress.—*La Presse Médicale.*

Psychiatry, War, and Revolution.—Laignel-Lavastine's lecture with this title, reported in *Le Progrès Médical*, xlix, 22, bristles with data which are frequently hackneyed concerning historical psychopaths. Many writings along these lines by earlier authors are freely mentioned. A distinction is sharply drawn between mental contagion and collective psychosis. Psychopaths come to the fore in war and revolutions. The question as to whether they actually bring about wars and revolutions is not so easily answered. There is no doubt the the German Kaiser was psychopathic, but his part in bringing about the war, *i.e.*, whether he was an instigator or a puppet, is not clear. The true motive was perhaps the "collective Teutonic paranoia," evidences of which are traced back to the time of Tacitus. On the other hand, if we accept the views of Lombroso and others that revolution is merely an expression of evolution, a distinction is offered between war and revolution, which may even be diametrically opposed, war being regressive and destructive while revolution is progressive and constructive. Such a distinction might not work out satisfactorily. It is quite possible to have constructive war and destructive revolution. The two, therefore, must be considered jointly. Both produce states of emotional disturbance and psychoneuroses, so that we may not be able to determine whether psychopathy in certain subjects contributed to war and revolution or was the result of the same. A distinction must therefore be made between antecedent and sequential psychopathy, which may not be easy; since the former may contribute strongly to the latter. There were well-known psychopathic characters who contributed to the French Revolution. There was even a rumor that a certain woman had Robespierre under hypnotic control, which legend shows the popular belief that the leaders of the Revolution were obsessed by some outside influence. Conversely, Charlotte Corday was but one of several women who sought to assassinate the revolutionary leaders. The counter-revolutionist who faces certain death in attempting the assassination of the revolutionary leader belongs to the martyr type, which is rife during religious persecutions.

THYROID ACTION AND FEVER.

BY E. H. P. WARD, A.B., M.D.,

WHITE PLAINS, N. Y.

IN the ganglia at the base of the brain, where the afferent paths terminate in the thalamic region, is located the chief executive center of the organism where sensory impulses from within and without the body are received, the situation sized up as indicating bodily well-being and security or the reverse, and the appropriate reactions immediately set up to meet whatever conditions or emergencies may exist; these reactions being subject to modification or inhibition by the lower reflex centers, and also by the higher cortical centers to which the sensory impulses may be immediately relayed. The thalamic executive center has at its command two types of reaction with which to meet unfavorable conditions which may arise from within or without the organism in the form of excessive heat and cold, physical danger or injury, or poisons in the alimentary tract or in the blood and tissues: the *active* type of reaction involving activity of the voluntary muscles, and the *passive* type in which voluntary activity plays no part.

The active type of reaction requires complicated adjustments of the bodily mechanism to provide for the pressure and distribution of the blood, the supply of fuel and oxygen, the increased muscular tone, etc., necessary for the more or less violent and prolonged muscular and mental exertion involved, and the thalamic center can effect these adjustments instantly by direct nervous control. But it can *sustain* them more easily and economically by increasing the secretion of *adrenaline* which has been developed by the organism for this specific purpose and which acts, without the expenditure of nervous energy, directly on the appropriate muscle and gland cells and on them only, leaving the executive thalamic center free to devote its attention to more important matters. And in addition to responding thus to excessive sudden or prolonged demands, adrenaline is probably secreted continuously in small amount to provide for the normal vascular tone and muscular activity of the body.

Now this adrenaline adjustment is remarkable for its simplicity and effectiveness, but it has a disadvantage in that once effected it is no longer under nervous control; the adrenaline, once secreted into the blood, remains there until used up in accomplishing its specific purpose. Hence if it becomes necessary to change quickly from an active to a passive state, and these adjustments maintained by adrenaline have to be modified or reversed, the adrenaline already in the blood or continuously secreted becomes an obstacle; which may indeed be overcome by active vasodilatation, etc., but this is a waste of energy if it has to be sustained for any length of time. It seems, however, that special provision for this difficulty is made by the *thyroid secretion* which plays the leading rôle in reactions of the passive type and by first neutralizing adrenaline clears the field for other adjustments. And since so important a part of thyroid action consists in neutralizing adrenaline, it is desirable to review briefly the effects of the latter.

Adrenaline accelerates and strengthens the heart beat and constricts the splanchnic and skin vessels but leaves the pulmonary and cerebral vessels dilated and even increases vasodilatation in the voluntary muscles; it dilates the bronchi widely and by stimulating the hydrolysis of glycogen in the liver increases the sugar in the blood. Thus muscular and mental activity are provided for. The vessels of the kidneys are at first constricted along with the other abdominal vessels, but dilate again while the blood-pressure is still at its height in time to eliminate the waste products of this activity in a flow of urine made abundant by this combination of high blood-pressure and renal dilatation. Meanwhile the gastrointestinal functions—both digestive and excretory—are suspended by the adrenaline, which causes cessation of the movements of the stomach and intestine and relaxes them to their full extent while contracting the pyloric, ileocolic, and internal anal sphincters and the muscularis mucosa, relaxing the gall-bladder and constricting the gall-duct; and the secretions of the digestive tract are minimized by the splanchnic ischemia (Cushny). This relaxing of the abdominal viscera and emptying them of blood makes them less liable to injury during severe muscular exertion, and the closing of the sphincters keeps the intestinal contents from being regurgitated or expelled by the pressure of the strongly contracted abdominal muscles. Adrenaline probably increases the tone of the voluntary muscles and when called forth in excessive amount by cold or in anticipation of great muscular effort, it may produce the involuntary movements of shivering, chattering of the teeth, and rigors; the shivering and trembling of an athlete before a contest, or of a soldier before a battle, being probably due directly to excessive adrenaline action. Adrenaline also produces a characteristic effect on the eye which serves to increase the field of vision and provides for the wide-awake alertness which ac-

companies muscular and mental activity; and the increased flow of tears washes the cornea to provide for sharpness of vision. The tears also warm the cornea, and the increased flow of watery saliva keeps the throat moist when breathing dry cold air.

The action of adrenaline on the vessels of the skin is of special interest and presents certain peculiarities. The skin vessels are constricted by adrenaline and the secretion of sweat minimized, and thus the skin is thrown out of action both as an excretory and as a heat-dissipating organ. In the excessive adrenaline action called forth by cold and by the excitement preceding great activity, this constriction of the skin vessels may be extreme, causing blueness and chilling of the surface especially in the extremities, and may be accompanied by contraction of the *erectores pilorum* muscles, causing the hair to be ruffled up in animals and goose flesh in man; but ordinarily the skin vessels are not so strongly constricted as the splanchnic vessels, and this is probably an adaptation to cold. In the presence of excessive cold the thalamic center, reacting to thermal impulses from the skin, stimulates an abundant secretion of adrenaline which by increasing muscular tone causes shivering or rigors, which may almost imperceptibly pass into more or less purposeful voluntary movements, and thus increases heat-formation; and by simultaneously contracting the skin vessels and the erectores pilorum and suspending perspiration, minimizes heat-dissipation; and thus the body temperature is raised. But as soon as heat can be spared from the interior, the skin must be warmed up too; and this is probably effected by the cold air acting as a skin-irritant and reflexly dilating the skin vessels, thus allowing the hot blood to flow through them and warm up the skin. And since the skin is practically always exposed to air below 98 F., it seems probable that the skin vessels are constantly reflexly dilated to a greater or less degree by the irritant action of cold; and thus their normal caliber would represent the resultant of the opposing forces of adrenaline constricting them and cold reflexly dilating them, and adrenaline could completely constrict them only when present in excessive amount. Of course in civilized man, wearing clothing, this condition would obtain principally in the exposed parts—the face, neck and hands. Thus, I believe, we may explain the action of adrenaline on the skin vessels, and especially those of the face; it is constantly counteracted by an active vasodilatation produced reflexly by the irritating effect of cold. This explains the remarkable but well-established fact that when the vasoconstricting action of adrenaline is counteracted by any cause not strictly localized, it is always the skin vessels which dilate first and always those of the face and neck before the rest of the skin. Thus the vasodilatation in *blushing* occurs first in the face and neck, and many drugs flush the face first and do not cause flushing of the rest of the skin unless their action is prolonged. *Amylnitrite* is perhaps the best example; inhaled and carried in the blood to all parts equally, it always dilates the skin vessels of the face first; if more of it is inhaled, it flushes the rest of the body; while in large amount, it finally finds its way into the more tightly constricted splanchnic vessels and by dilating them causes a marked fall in blood-pressure with throbbing of the arteries, weakness, faintness, etc. The *thyroid secretion* is no exception to this general rule, and when it neutralizes adrenaline the blood-vessels dilate first in the face, then in the rest of the skin, and finally in the splanchnic area.

The thyroid secretion must neutralize adrenaline chemically or counteract it physiologically, for in its presence the adjustments effected by adrenaline are reversed. Da Costa ("Modern Surgery") considers the condition of myxedema due largely to the effects of adrenaline unopposed by the thyroid secretion, and adrenaline is beneficial in exophthalmic goiter. In conditions of hyperthyroidism the tissues, deprived of adrenaline, lose their tolerance of it and their reactions to it become exaggerated. Judging from disorders due to its deficiency or excess, and from the results of its therapeutic and experimental administration in man and animals, the thyroid secretion produces the following effects:

A. Effects due to neutralizing adrenaline:

1. General muscular weakness, especially in lower limbs.

2. Pigmentation of the skin (see my Notes on Adrenal Action, MEDICAL RECORD, Nov. 20, 1920).

3. Circulatory effects: dilatation with throbbing of the heart and blood-vessels, with lowered blood-pressure and acceleration of the pulse (tachycardia) to compensate for the impaired circulation; first the skin vessels are dilated (first in the face and neck, then in the body and limbs) and this results in flushing of the skin with profuse perspiration, and if prolonged to edematous infiltration of the skin with extravasated serum (erythema); there may be headache (cf. amylnitrite); later the splanchnic vessels are dilated, leading to congestion of the abdominal viscera which, if of moderate degree, leads to diuresis; if of greater degree, to renal congestion with albuminuria and to gastrointestinal catarrh with anorexia, indigestion, and constipation; while if intense, this splanchnic congestion leads to gastroenteritis with nausea, vomiting and diarrhea, nephritis, and fatty degeneration of the internal organs, with perhaps delirium (from cerebral anemia) and collapse; the thyroid secretion by neutralizing the relaxing effect of adrenaline on the walls of the stomach and intestine, and its constricting action on the sphincters, prepares for the peristaltic movements of vomiting and diarrhea which are probably reflexly stimulated by the intense congestion, as in failure of the right heart. *Thirst* results from the loss of water from the blood by perspiration, extravasation of serum into the skin, etc., diuresis and diarrhea.

4. The respiration is rapid and shallow, which may be partly an adaptation to the circulatory changes; but the chest expansion may be greatly diminished in exophthalmic goiter and in fever, and this may be due to a weakening and loss of tone of the respiratory muscles resulting from lack of adrenaline. An exaggerated form of this type of respiration is seen in panting, laughing and crying.

5. The thyroid secretion may directly stimulate the sweat-glands, the kidneys, and the gastrointestinal mucosa, or the increase in these secretions may possibly be accounted for by the passive or reflex influence of the hyperemia.

B. Other effects of the thyroid secretion:

1. It is supposed to exert a *solvent* or autolytic action on toxic substances in the tissues, comparable to the action of the iodides on gummatous tissue, etc., and due to its iodine content.

2. It has a remarkable specific action on *metabolism*, increasing the combustion of carbohydrates, fats, and proteins (including even the proteins of the tissues), as shown by the increased consumption of oxygen and elimination of CO_2, the increased elimination of N. P., etc., in the urine, and the disappearance of glycogen from the liver which may be so rapid as to overload the blood with sugar and cause glycosuria. This increased combustion leads to a rise of temperature and may cause fever even in spite of the rapid heat-dissipation from the flushed and perspiring skin. And the destruction of body proteins (which can be prevented by a rich protein diet), along with the increased combustion of fats and the loss of water by sweating, diuresis, and diarrhea, leads to a rapid loss of flesh and weight.

3. Thyroid secretion in excess causes *tremor* in the arms and legs, and even choreiform movements; this may result from interference with the parathyroids, or it may be that sodium (chloride) is retained in greater proportion than calcium in the extravasated serum and, by displacing calcium in the nerves, leads to irritability.

4. Hyperthyroidism is often accompanied by wandering pains, neuralgia, etc.

5. Prolonged hyperthyroidism (exophthalmic goiter) in young persons generally leads to persistence of the *thymus* gland with hypertrophy of its lymphoid tissue and lymphocytosis. Apparently the thyroid secretion exerts some stimulating chemical or other effect on the thymus, for after thyroidectomy this hypertrophy and lymphocytosis subside.

6. There seems to be no good evidence that the thyroid secretion ever directly produces *exophthalmos*, nor does thyroidectomy cure this condition in exophthalmic goiter. It is probably due to active congestion of the loose orbital tissues, especially the lachrymal glands, and is produced by direct nerve control independent of, but in certain cases associated with, the stimulation of the thyroid gland which produces hyperthyroidism.

The reactions of the passive type, in which the thyroid secretion plays so important a part, are characterized by a more or less complete reversal of the adjustments for muscular activity produced by adrenaline, and a more or less complete suspension of voluntary activity with a lowering of muscular tone. This leads to a great reduction in heat-formation, and it is to compensate for this and keep the body at the normal temperature that the thyroid secretion stimulates combustion; which is no longer in the muscles principally but in the tissues of the body generally and especially in the liver, and which uses up fats and proteins as well as carbohydrates; and which is all the more necessary on account of the increased loss of heat produced by the thyroid secretion. Not all of the effects of the thyroid secretion seem to be of value in every reaction in which it is called forth, and some of its effects (*e. g.* the tremor) seem to be of no value in any reaction. This secretion is like a "shot-gun" prescription, adapted to many different purposes but not exactly to any one purpose. The passive reactions in which it is concerned are the following, its increased activity being usually indicated by a transient swelling or congestion of the gland providing for increased formation and absorption of the secretion:

I. *Violent or prolonged muscular effort* may cause congestion of the thyroid gland, and the secretion may in this case serve two purposes:

A. It may have a *safety-valve* action, relaxing the constricted blood-vessels and thus lowering the resistance against which the heart has to work, in case the latter becomes fatigued or exhausted; cardio-inhibition providing for temporary relief until the thyroid secretion has time to act. The effect of the secretion is to dilate the skin vessels with flushing and perspiration of the face and body (which may be a "cold sweat" if the body is not overheated), increased pulse-rate, and muscular relaxation and lassitude. If the action is more marked, dilating the splanchnic vessels too, there may be faintness, nausea with perhaps vomiting, prostration, throbbing of the heart and arteries, dyspnea, and even collapse.

B. The *heat-dissipating* action of the thyroid secretion may be called upon if the body temperature is raised above normal by violent or prolonged muscular exertion. Ordinarily it dilates only the skin vessels with flushing and more or less profuse perspiration, first of the face and neck and hands, then the rest of the body; accompanied by slight muscular relaxation and lassitude, which diminishes heat-formation. But if the heat is excessive, as in hot weather, the thyroid secretion may be stimulated in larger amount and, in addition to free perspiration, cause splanchnic dilatation with lowered blood-pressure, throbbing heart and blood-vessels, accelerated pulse, panting respiration, muscular weakness, and perhaps faintness and nausea; or even giddiness, vomiting, diarrhea, and collapse with coma—the symptoms of heat-exhaustion, the blood collecting in the splanchnic area and leaving the skin pale and cold because still wet from the preceding perspiration. In hot weather the neck is liable to swell from congestion of the thyroid gland, which is stimulated to activity in order to provide for free circulation in the skin and free perspiration as a means of heat-dissipation to keep the body cool. And, paradoxical as it may seem, the thyroid secretion by increasing combustion provides for maintaining the normal body temperature during weather too warm or too humid for muscular exertion. For during such weather the temperature, while too high to permit of muscular exertion (which would produce far too much heat), is still as a rule considerably below 98° F. Hence the body slowly loses heat to the surrounding air, and it is only by the action of the thyroid secretion that its temperature is maintained at normal. And it is because this action increases combustion of the body fats and proteins that it leads to loss of flesh during hot weather, and an increased demand for protein foods to spare the tissue proteins; and this is why lack of exercise leads to loss of weight—during inactivity the body-temperature is maintained by the action of the thyroid secretion at the expense of the proteins of the tissues; perhaps it

interferes with protein anabolism and thus liberates an excessive amount of intracellular heat (see my Notes on Motility, MEDICAL RECORD of August 21, 1920). In cretinism and myxedema the skin is dry, there is a complete absence of perspiration; and it is said that in conditions of chronic mild hypothyroidism the skin may not perspire noticeably even after severe exertion in hot weather.

Thus the thyroid secretion serves to adapt the organism to high external temperatures, by virtue of both its heat-dissipating and moderate heat-producing effects; just as adrenaline serves to adapt the organism to low temperatures by virtue of its heat-conserving and great heat-producing action. These two agents constitute the heat-regulating mechanism of warm-blooded animals, both being controlled by the executive thalamic center in response to heat and cold stimuli acting on the skin. [Some animals which do not perspire freely provide for heat-dissipation by evaporation from the lungs, the rate of respiration being increased in the dog from 15 to as high as 300 per minute; this too may be an effect of the thyroid secretion—an exaggerated effect of its usual action in producing rapid and shallow respiration (panting) which even in man increases heat-dissipation.] It is said that when the thalamic region is cut off from the lower portions of the central nervous system, a fall in body-temperature produced by cooling of the surface no longer stimulates the reaction of shivering, nor does septic infection any longer produce fever. And lesions in the neighborhood of the basal ganglia (heat puncture) cause a marked rise in temperature, and this occurs after the muscles are paralysed by curare but not if the liver is free of glycogen; and this rise of temperature is the result of an increased combustion not only of carbohydrates but also of proteins. Therefore it seems probable that this hyperthermy following heat puncture is due to the action of an increased thyroid secretion stimulated directly by this injury to the region from which the thyroid is controlled. Hot baths also induce hyperthermy by increasing combustion, including destruction of tissue proteins, and this too is probably a result of an increased thyroid secretion stimulated by the heat.

II. The thyroid secretion plays a leading rôle in the passive reaction to danger, mental shock, and physical injury in cases where these emergencies cannot be met by voluntary activity.

A. The *freeze-reaction*, which may be accompanied by the conscious emotion of fright, fear or anxiety, constitutes the passive reaction to danger, and *exophthalmic goiter* is merely this reaction abnormally prolonged. When an animal receives a stimulus which signifies or suggests danger, it may do one of three things: (1) It may run away; (2) it may advance to investigate or attack; or (3) it may become immobilized or "freeze"; and any of these reactions may be accompanied by fear. The sensory paths are broken up into relays on their way to the cortex because many of the adaptations called for by sensory impulses can be effected by local reflexes more rapidly and more economically without unnecessarily disturbing the higher centers. Now the ganglia in the thalamic region constitute the last and most extensive relay station where all afferent paths converge and terminate on their way to the cerebral cortex, both the main sensory tracts from the cord and also the tracts from the organs of special sense. Thus the nuclei of the thalamic region constitute a higher reflex center where all sensory impulses from within and without the body are received, compared, and coordinated, and the general systemic reactions to them are instituted. Many of these reactions, such as those adapted to excessive heat or cold, poisons in the alimentary tract or blood and tissues, and to a large extent the reactions (which we are considering under this heading) to danger, mental shock, and physical injury, are carried out without the knowledge or assistance of the cortical centers, which may indeed become aware of them only objectively, from their results, if at all (while on the other hand many of these systemic reactions may be modified or supplemented by local reflexes from the lower centers in the medulla, cord, and peripheral ganglia). And even when the afferent impulses are relayed from the nuclei of the thalamic region to the cortex, in order to bring to bear upon the case the more specialized judgment of the cortical centers, or to call upon the motor cortex for voluntary activity, the thalamic center must meanwhile arrange for the fundamental adjustments of the bodily mechanism which are a necessary preparation for this activity; or perhaps provide for a complete suspension of voluntary activity, as in the case of the freeze-reaction.

Thus when a stimulus indicating danger is received the thalamic center immediately relays the message to the cortex (where it may arouse the conscious emotion of fear), and meanwhile instantly effects the adjustments for the reaction, active or passive, which it judges best suited to the emergency, its judgment being subject to review by the higher cortical centers. These adjustments are effected immediately by direct nervous stimulation or inhibition, but their continuation is provided for by adrenaline or the thyroid secretion. Thus, when an animal runs away or fights, the violent and prolonged muscular exertion involved is provided for by an abundant secretion of adrenaline which produces its characteristic effects, including perhaps contraction of the *erectores pilorum* muscles, which in man cause goose-flesh and a chilly creepy feeling along the spine, but in animals makes the hair stand on end, serving to make the animal seem larger and more formidable, and also to reduce the force of blows and confuse their aim.

If, on the other hand, the animal freezes, this passive type of reaction requires complete and perhaps indefinitely prolonged immobility and, while it is no doubt initiated by instant reflex inhibition, its continuance must be provided for by an increased thyroid secretion—especially if adrenaline happens to be left over in the blood in large amount from a preceding state of activity; for it seems impossible for an animal strongly under the influence of adrenaline to remain perfectly motionless for any length of time.

Thus the freeze-reaction is instituted by sudden inhibition — cardiac and muscular — the "heart stands still" and the animal is "paralyzed with fear." Then the thyroid secretion is stimulated and the gland becomes acutely congested, causing a sense of constriction and fullness and a

throbbing in the throat—the "heart beats in the throat"; the secretion is poured into the blood, neutralizing adrenaline and lowering blood-pressure, and the heart and arteries throb and the pulse becomes accelerated; the skin vessels are dilated and the face and body may be flushed for a moment and "beads of perspiration break out on the face" and body, but the rapidly succeeding splanchnic dilatation leaves the skin pale and cold and the condition becomes "a cold sweat"; the strength and tone of the muscles is reduced, especially in the legs, and the animal stands motionless and "rooted to the spot"; the erectores pilorum are fully relaxed and in animals this causes the hair to lie down very flat, making the animal seem smaller and less conspicuous; the respiratory movements become shallow and rapid and this limitation of movement helps the animal to escape detection—it is "afraid even to breathe," whereas when the danger is past it can once more "breathe freely"; in extreme cases the splanchnic dilatation may lead to faintness, nausea, vomiting, diarrhea, or even involuntary passage of urine and feces due to relaxation by the thyroid secretion of the adrenaline-constricted sphincters. The eyes protrude (exophthalmos) and this serves to increase the field of vision, and the eyes may even lose their convergence (cf. exophthalmic goiter) and roll around independent of one another sweeping the entire field of vision for a possibility of escape. Meanwhile the prolonged inactivity would lead to a great fall in body temperature if the thyroid secretion did not provide for increased heat-formation in its characteristic way, which may even cause a rise in temperature making the victim feverish from fear. Finally there is the tremor of fear (cf. exophthalmic goiter).

Now which one of these three reactions to danger—run, fight or freeze—a given individual or animal may show at a given moment in the face of a given danger depends upon the nature of the danger, the instinctive characteristics and past experience of the animal, and the circumstances of the moment. Generally speaking, an unknown or unfamiliar danger is more likely to produce the freeze-reaction, which enables the animal to escape detection while awaiting developments and weighing the circumstances in order to decide upon the safest course of action before committing itself to a retreat or a combat which might prove disastrous. There may be a period of indecision in which now one reaction, now another, may gain the ascendancy, and the incipient symptoms of the different reactions may succeed and replace one another in rapid succession, the chilly, creepy, goose-flesh feeling due to adrenaline alternating with the hot, flushed, perspiring skin due to the thyroid secretion and thus producing chills and fever. The mild reaction accompanying confusion known as *blushing*, while it may be due momentarily to reflex vasodilatation, is, when prolonged into the flush of embarrassment, probably due to an increased thyroid secretion; and here, as in all other cases of dilatation of the skin vessels, the face and neck are flushed first and perhaps alone. Hyperthyroidism seems to favor a condition of abnormal mental acuteness which serves in the presence of danger or difficulty to help find a way out. When the suspense is over there follows, especially in women, a "reaction" in which the exophthalmos is relieved by the shedding of tears and the rapid shallow respiration culminates in the movements of laughing or crying; the tears and the respiratory movements of laugning and crying are identical, and both are accompanied by swelling and congestion of the thyroid gland, being distinguished only by the facial expression and the mental emotion which accompany them. But if for any reason the suspense is prolonged, or if the thalamic center is overstimulated by the danger or difficulty, or if the higher cortical centers do not exert their normal control over the thalamic center, due, perhaps, to their failure to sublimate the emotion of fear, then the excessive or prolonged stimulation leads to the hyperthyroidism of exophthalmic goiter, the *exophthalmos* being due to the tension of unshed tears.

B. *Shock.*—If a sudden danger seems very great, the victim may faint from cardiovascular inhibition; or if after developing the freeze-reaction no way of escape is found and the danger seems more imminent, the splanchnic dilatation resulting from excessive thyroid action developing gradually will cause the victim to collapse from fright and "play 'possum." This is really a condition of extreme *shock;* and when shock comes on gradually or is of the delayed type, and when it is prolonged, it is no doubt due to excessive thyroid action. The symptoms of shock are identical with those of the freeze-reaction, only more severe and developing more rapidly and thus skipping some of the details. At first the pulse is slow in shock, from cardiac inhibition, but when the thyroid secretion becomes effective there is vascular dilatation with perspiration, which immediately becomes a "cold" perspiration, because the splanchnic dilatation collects the blood in the abdominal viscera, leaving the skin cold and pale and bloodless; the pulse becomes weak and rapid, the respiration rapid and shallow; and there is faintness, nausea, and collapse with relaxation of the sphincters, and perhaps vomiting as the strength returns. Fright, bad news, physical injury, especially if preceded by fear of injury, may cause immediate collapse, even instant death—probably by cardiac inhibition. But a preexisting hyperthyroidism, whether due to fear or other causes, as toxemia, is a factor strongly predisposing to shock even though it has previously given rise to no symptoms; and severe shock is especially liable to occur in exophthalmic goiter during anesthesia or operation, and the "thymic death" is probably a death from shock intensified by a condition of hyperthyroidism. Then, too, shock may result directly from the effects of the thyroid secretion, as when during thyroidectomy some of the colloid material is absorbed from the wound and induces severe or fatal shock; and it may even produce an elevation of temperature—*thyroid fever.*

The temperature in shock is usually subnormal, probably as a result of the increased heat loss by free perspiration in its early stages and the complete collapse which follows. Ordinarily this chilling would lead to increased adrenaline secretion with rigors, etc.; but this would be fatal in the case of shock resulting from wounds, because it would increase hemorrhage, and one of the main uses of shock is to lessen hemorrhage. And it takes time for the heat-producing action of the thyroid secretion to become effective, especially in a state of pro-

found collapse with everything at a standstill. But this action may produce fever following shock in cases where the physical injury is comparatively slight and the shock is of the nervous type, and this so-called *emotional* fever not infrequently follows accidents and operations and may be preceded by a chill and accompanied by hysterical excitement. Hysterical fever is probably of this type, and the inexplicable elevations of temperature which may occur in neurasthenia. And the aseptic *traumatic fever*, or post-operation rise of temperature, which often appears after aseptic operations, or after a contusion or simple fracture, with no preceding chills or indisposition, is probably a result of the heat-producing property of the thyroid secretion following shock; and the *fever of tension* from stitches may be of a similar nature. Sometimes after operations in hot weather the symptoms of *sunstroke* develop, due probably to the combined effects of shock and of excessive heat in stimulating hyperthyroidism and diminishing adrenaline secretion.

Thus shock is due to an excessive thyroid secretion called forth in a passive mode of reaction—an exaggerated form of the freeze-reaction—evolved by the organism as a means of meeting dangers, or pain, or physical injury which it cannot actively combat; and if this secretion is already present in excess as a result of fear or of hyperthyroidism from any other cause, it takes less of a stimulus to increase it to the point necessary to produce shock. And since the thyroid secretion produces shock largely by neutralizing adrenaline, any condition such as fatigue or hunger or heat which implies a scarcity of adrenaline predisposes to shock. Thus bad *morale* predisposes to shock by diminishing adrenaline through fatigue or hunger or excessive heat, and inducing hyperthyroidism through the effect of uncertainty, anxiety, worry, fear, pain, or physical injury. Shock is nature's method of inducing anesthesia, controlling hemorrhage, and limiting injury, and extreme shock may save the life of an animal by enabling it to "play 'possum" and be mistaken for dead; and as a last resort, it at least assures a painless death.

III. There is little essential difference between the effects of gross physical injury and of the chemical injury which results from the action of poisons swallowed or produced in the gastrointestinal tract, or circulating in the blood; at any rate, these latter conditions seem to call forth the same reaction—an increased thyroid secretion, which here makes the most complete use of its many effects.

A. In the *emetic* and *purgative* actions, which are characteristic effects of so many poisons when formed in, or introduced into, the alimentary tract, while the actual movements which empty the stomach and bowel and some of the increased secretions are no doubt due to reflex action, it seems probable that an increased thyroid secretion clears the field for these reactions by neutralizing the effect of adrenaline on the gastrointestinal tract and the splanchnic vessels. Under adrenaline the alimentary tract is fully relaxed, thrown out of action, and locked up by the sphincters and drained of blood; and certainly this whole condition must be reversed to allow of the emetic and purgative actions, especially if much adrenaline happens to be present in the blood. And while it might be reversed momentarily by direct nervous control working against the locally-acting adrenaline, this would be a waste of nervous energy, especially if prolonged. This emetic action is characterized by profuse salivation with increased mucous secretion by the nose, throat, and bronchi, tears, and cold perspiration; also depression and muscular weakness with acceleration of the pulse, passing perhaps into prostration and alarming or fatal collapse. Nausea and vomiting result if the poison is sufficiently concentrated and soluble in the stomach, purgation from its effects in the intestine if it reaches there. Many of these substances are excreted into the intestine from the blood and exert their irritant action if introduced in this way. The activity and congestion of the alimentary tract with the accompanying symptoms of vasodilatation certainly indicate that the adrenaline adjustments are no longer maintained; and it seems reasonable to infer that here, as in the other passive reactions, they are reversed by an increased thyroid secretion, although reflex dilatation of the splanchnic vessels at the start may hasten and intensify the local action of this secretion.

Practically all irritant poisons, if in sufficient quantity and concentration, and not too insoluble in stomach or intestine or too quickly absorbed into the blood, produce this emetic or purgative action, or both; while many of them (as phosphorus, arsenic, and the heavy metals) are also absorbed and, gradually excreted back into the alimentary tract or deposited in the liver, etc., exert a continued irritation, resulting in a prolonged hyperthyroidism characterized by vasodilatation with gastrointestinal congestion and catarrh, or even gastroenteritis, the disappearance of glycogen from the liver, fatty degeneration or infiltration of the internal organs, increased destruction of tissue proteins, and often more or less fever. But many of these irritant poisons, such as certain of the alkaloids, exert after absorption into the blood a specific action on various parts of the central nervous system, the heart, and the peripheral organs—the latter sometimes resembling in its mode of action the effects of adrenaline; and these effects often complicate and mask the emetic action. The toxin of cholera is an instance of a bacterial poison with this local irritant action on the gastrointestinal tract, and indigestion with fermentation and decomposition of food may have a similar effect. Very often in conditions of prolonged gastrointestinal irritation *tetany* develops, especially in children, and may result from interference by the thyroid secretion with the parathyroids.

The passage of gallstones presents a remarkable example of the specific action of the thyroid secretion in favoring the elimination of foreign substances from the gastrointestinal tract. Under adrenaline the gall-bladder is relaxed and would not expel a stone, while the gall-duct is constricted so a stone could not pass; but the thyroid secretion by neutralizing the adrenaline allows the gall-bladder to contract and expel the stone, and relaxes the gall-duct so the stone can pass. But meanwhile the excessive thyroid secretion brings on the exaggerated symptoms of shock and collapse so characteristic of gallstone colic, and there may be fever from the thyroid action.

B. *Fever.*—The febrile reaction is essentially a condition of more or less intense and prolonged

hyperthyroidism stimulated by the thalamic center in response to the irritant action of poisons in the blood and tissues. As usual, the thyroid action sends the blood to the skin and splanchnic area, opening up the avenues of elimination, and the usual circulatory and other symptoms attend this action, including the characteristic increase of combustion to keep up the body temperature during this period of enforced inactivity. If the poisons are readily eliminated by the sweat-glands, kidneys, and bowel, the actual hyperthermy is not marked or prolonged; but if the toxins are too virulent to be excreted at once—"too hot to handle"—and paralyze or inflame the excretory organs, then the characteristic symptoms of the febrile reaction are developed in the skin, the kidneys, and the gastrointestinal tract; and the absence of perspiration combines with the vasodilatation and serous infiltration of the skin (slowing circulation and acting like a water-jacket) to reduce heat-dissipation; and this, in conjunction with the increased combustion, produces the febrile temperature. There are five reasons for supposing that the thyroid secretion is instrumental in producing the febrile reaction:

(1) The thyroid gland is often congested in febrile conditions, presumably indicating increased activity.

(2) The gland not infrequently atrophies during or after fevers, especially the acute infectious fevers, presumably from exhaustion due to overactivity. And even when it does not noticeably atrophy, it may become functionally insufficient, and this is considered the chief cause of chronic mild hypothyroidism.

(3) Fever is a reaction to toxemia and the thyroid secretion seems to play an important part in combating toxemia, many cases of goiter and hyperthyroidism being presumably due to excessive demands upon the thyroid gland made by chronic toxemia of intestinal or other origin.

(4) With certain modifications due to the toxins, the characteristic features of fever and of hyperthyroidism are identical—the vasodilatation with full bounding pulse and tachycardia, low blood-pressure, rapid and shallow respiration (the chest expansion may be diminished in fever as in exophthalmic goiter—see Carpenter and Benedict, *Amer. Journal of Physiology*, May 1, 1909), the flushing of the skin, especially of the face, with profuse perspiration and serous infiltration (erythema), the abundant secretion of urine; the wandering pains, weakness, prostration, headache, and delirium; the gastrointestinal catarrh with anorexia, indigestion and constipation, and perhaps nausea, vomiting, and diarrhea; the thirst, loss of flesh, elevation of temperature; the general characteristics of the metabolism, with increased consumption of oxygen and elimination of CO_2 attending the increased combustion of carbohydrates and fats and also of proteins, including the proteins of the tissues which can be spared by an abundant protein diet, the disappearance of glycogen from the liver with the occurrence of sugar in the urine ("toxic" glycosuria), the fatty degeneration or infiltration of the internal organs; the anemia, the tremors and choreiform movements or tetany, the changes in the thymus gland—a most remarkable coincidence, to say the least.

(5) The action of the thyroid secretion is especially adapted to ridding the blood and internal organs of toxins because, in addition to whatever solvent or autolytic action it may have on toxic substances, it opens up the great avenues of elimination—the kidneys, the skin, and the gastrointestinal tract. Under adrenaline the kidneys are active in excreting the normal waste products of metabolism for which they are specially adapted; and while they may be able to excrete other substances as well, they cannot excrete any substance without concentrating it in the renal tubules whose cells are highly specialized and therefore delicate and with comparatively little power of regeneration, and concentrated toxins are likely to injure them beyond repair; and under adrenaline the skin and alimentary tract are thrown out of action and locked up. But the thyroid secretion not only favors renal activity but also brings into action the great eliminating powers of the skin and gastrointestinal tract which are more generalized and can excrete substances which the kidneys cannot; and these excreting epithelia, in the sweat-glands and mucous membrane, present extended surfaces from which the toxins can be excreted rapidly and without becoming concentrated, and even if injured by the toxins they have great powers of resistance and regeneration; furthermore, they constitute in the capillaries and loose areolar tissue of their subepithelial layers a reservoir of immense capacity in which the toxins dissolved in extravasated serum can be collected from the more vital and delicate internal organs and safely deposited awaiting excretion.

This getting the toxins out of the general circulation and away from the delicate and vital internal organs is of great importance in case they are too virulent to be excreted at once by the kidneys, gastrointestinal mucosa, and the sweat-glands, which may be paralyzed or inflamed by their presence. In the kidneys they often cause more or less irritation or inflammation, as shown by the scanty, high-colored urine, albuminuria, or even nephritis; and in the gastrointestinal tract they may intensify the catarrh already present from congestion. But the kidneys and gastrointestinal tract are usually spared from severe injury because the toxins are deposited principally in the skin, as a result of the fact that the skin vessels are dilated first under the influence of the thyroid secretion. This dilatation of the skin vessels is accompanied by relaxation of their walls and slowing of the blood current which permit the serum, carrying the toxins in solution, to escape into the loose subcutaneous areolar tissue, causing the skin to become hot, red, swollen, perhaps tense and edematous; and as a rule this erythematous condition occurs first and is most marked in the face. The toxins thus collected in the skin cause more or less irritation and inflammation, and not only interfere more or less with perspiration, but may cause the skin to become tender or itching, often leave it stained and cause it to peel off, and not infrequently cause localized areas of gangrene, especially where there is continued pressure (bed-sores). (Sometimes, in the absence of perspiration, the toxins may perhaps be partly discharged from the skin in gaseous form, giving the characteristic odors from the skin in typhoid, typhus, etc.) The heat-dissipating function is also more or less diminished as a result of this condition. In the first place, per-

spiration is more or less completely suspended and the skin becomes dry; this diminishes heat loss by evaporation. Then, too, heat loss by convection is interfered with by the sluggish circulation in the skin resulting from the vasodilatation with slowing of the blood stream, and as the extravasated serum accumulates in the skin it may compress the blood-vessels and thus reduce the circulation still further. And, finally, the edematous skin acts, like a water-jacket around the body, to diminish heat loss by conduction and radiation. And the accumulation of serum in the skin concentrates the blood and leads to thirst, and chlorides are retained in the body to preserve the isotonicity of the blood and also of the extravasated serum. It may be that sodium is retained (as a chloride) in greater proportion than calcium and, by displacing calcium from the nerves, causes the tremor and tetany which sometimes occur in prolonged fevers; or it may be that the thyroid secretion is directly responsible for these symptoms, through interfering with the parathyroid secretion. The importance of depositing the toxins in the skin is seen in those cases in which it fails. Thus scarlet fever in some individuals, and with especial frequency in some epidemics, may not be accompanied by much, if any, fever or rash; that is, the toxins are not deposited in the skin. The case is considered to be very mild until a perhaps fatal nephritis develops; the toxins have become concentrated in the kidneys instead of the skin.

When the toxins accumulate gradually in the blood and tissues, they stimulate a gradually increasing thyroid secretion which, by dilating the skin vessels only, gradually produces a serous infiltration of the skin just as in exophthalmic goiter; and as the toxins dissolved in this extravasated serum become concentrated in the skin, they paralyze the sweat-glands and the fever gradually rises as a result of the diminished heat-loss and the increased heat-production produced by the thyroid secretion. This occurs during the stage of invasion of fevers with a gradual onset, and may also cause the temperature to rise again after remissions or intermissions during a continued fever. But when the toxins enter the blood and tissues suddenly and in large amount, they seem to interfere with metabolism by their concentrated effect, and the result is a lowered combustion in the tissues and a fall of body temperature. This stimulates adrenaline secretion and results in sensations of chilliness or a distinct chill with perhaps rigors (convulsions in children). This leads to excessive heat formation and the temperature rises rapidly to a point above normal. Then the thyroid secretion is greatly increased in response to both the toxemia and the hyperthermy, and by dilating the skin vessels while the splanchnic vessels are still constricted by the adrenaline and the blood-pressure is still high, causes the toxin-laden blood to be pumped through the skin vessels at high pressure. And if the toxins can be eliminated readily, there is a profuse perspiration which carries them off along with an abundant flow of urine; but if the toxins are very virulent, they paralyze the excretory epithelia and instead of being excreted in the perspiration they are forced along with extravasated serum into the loose subcutaneous tissue, producing a febrile erythema. This often occurs at the onset and also during the course of fevers when toxins are newly absorbed; and this alternate action of adrenaline and the thyroid secretion is remarkably adapted to rapidly ridding the blood and tissues of toxins, squeezing them out of the tissues like rinsing a sponge and injecting them into the skin. In addition to this passive dilatation of the skin vessels by the thyroid secretion, the vessels in more or less limited areas of the skin may be actively dilated by a reflex mechanism similar to that involved in the production of referred pains. Thus the internal organs which are most susceptible to the toxins, or in which they become most concentrated, reflexly cause active vasodilatation in the corresponding skin segments, causing the toxins from the blood to be deposited in greater amount in these circumscribed areas than in the intervening skin; and in these areas, concentrated about the sweat-glands, the toxins act as more or less severe skin irritants producing macules, papules, vesicles, and perhaps pustules, which may become confluent; sometimes they cause an urticarial rash, or they may injure the capillary walls and cause hemorrhages in the form of petechiae, ecchymoses, or a widespread hemorrhagic condition. Thus the skin rashes characteristic of certain fevers result, their distribution and order of appearance depending on the internal organs most affected by the toxins. Thus in pneumonia the face may be flushed only on the side corresponding to the affected lung, and in bronchial asthma the urticarial rash may be confined to the interscapular region.

The intensity, course, and duration of a fever depend on the amount of toxins deposited in the skin, their virulence, and the rate at which antitoxins are formed to neutralize them. As the toxins are neutralized they can be excreted by the sweat-glands, kidneys, etc., and this may occur by degrees during the course of the fever leading to sweats with remissions or intermissions; or it may occur gradually at the end of the fever, which falls by lysis; or suddenly, when the fever falls by crisis with a critical diaphoresis, diuresis, or diarrhea. Fevers which fall by crisis generally are sudden in their onset (malaria, pneumonia, typhus), probably because the same sudden concentration of toxins in the blood and tissues which produces the sudden onset, at the same time stimulates all the antitoxin-forming tissues to their full efforts simultaneously; and thus the antitoxins are formed suddenly and all at once, and the fever falls suddenly. The hyperthermy is said to favor the production of immunity. Probably the spleen, lymph glands, and bone-marrow are concerned in producing antitoxins; and the lymphoid tissues of the thymus gland probably constitute a special provision for the acute infectious fevers of childhood, the thymus gland not infrequently becoming atrophied after these infections.

Not all toxemias produce fever; sometimes the toxins are readily excreted under the influence of the thyroid secretion, and thus do not interfere with heat dissipation. Nor do all toxemias cause hyperthyroidism; the thyroid secretion may be insufficient or it may not be called upon as in those cases of scarlatina with little or no rash or fever, but with acute nephritis. It may be that the thyroid reaction to toxemia has been evolved as a reaction to particular toxins only, and if these toxins fail to be recognized no fever results. And finally there are

other general principles according to which toxins may be dealt with when they cannot be eliminated immediately.

NORTH STREET AND WARD'S LANE.

CANCER CONTROL.

BY SEELYE W. LITTLE, M.D.,

ROCHESTER, N. Y.

MEDICAL authority lays the greatest stress upon the removal of chronic irritations as a means of controlling cancer and reducing the death rate from cancer. This is the result of two things: (1) Medical authority's acceptance as a fact of the proposition that at first cancer is a purely local disease confined to the pathological new growth called cancer; (2) the undisputed fact that a cancer is more likely to appear at the site of such chronic irritation than elsewhere. Neither of these things warrants the assertion as a fact that cancer may be controlled by preventing or by removing such chronic irritations. Nor do both of these things warrant the assertion.

In the first place cancer has never been proven to be a local disease at any stage. Nor has cancer ever been proven not to be a constitutional disease at every stage. In the second place there is no evidence at all to show that prevention or removal or absence of such chronic irritation in any given locality lessens the numerical incidence of cancer or diminishes the cancer death rate. On the contrary, there is ample evidence to show that no such results follow the prevention, removal, or absence of chronic irritation in any given locality. It is undoubtedly true that removal, prevention, or absence of chronic irritation in a given locality lessens the chances of the appearance of a cancer *in that particular locality*. But that is quite another proposition than this, for example: "If a man past middle life does not smoke heavily, cares for his teeth, and keeps his mouth clean, he *is very much less likely to have cancer* than one who does not follow the simple laws of mouth hygiene." (Official pronouncement of The American Society for the Control of Cancer, March, 1920. Italics mine.)

That pronouncement is unsupported by any proof which the writer has ever been able to discover. It is strongly negatived by a vast amount of evidence. It is an opinion, not a demonstrated fact. A careful consideration of a concrete instance will, perhaps, best serve to make these points clear. Let us take cancer of the lip.

In 1914 in the Registration Area of the United States there were 376 deaths from cancer of the lip; males, 347 out of a total of 21,282 cancer deaths among males; females, 29 out of a total of 31,138 cancer deaths among females. It is universally admitted that males have cancer of the lip oftener than females in the United States; it is universally admitted that smokers have cancer of the lip far oftener than non-smokers; it is therefore well within the truth to say that if no person in the United States smoked there would be fewer cancers of the lip than there are; but from that truth it is a long, unwarranted step to allege that because there would be fewer cancers of the lip there would be a diminution in the total number of cancers. Let us see.

Smokers die from cancers other than cancer of the lip in the proportion of about 52 to 1, if the smokers happen to be white men in the United States; in the proportion of about 282 to 1 if they happen to be colored men. Without fear of contradiction it may be said that colored men smoke as often as white men in this country; it is evident therefore that there is some element other than chronic lip irritation which is more than five times as prevalent or powerful among male whites than among colored males so far as the production of lip cancer is concerned. Removing the lip-irritation from male whites, therefore, still leaves male whites far more liable to lip cancer than are colored males, whether they smoke or not! For as a matter of fact there were but two deaths from lip cancer all told among colored males in 1914 in the Registration Area of the United States, and I venture to say that out of the 345 male whites who died from lip cancer in the same area there were eight or ten non-smokers at least. This strongly suggests some racial, inherent, constitutional, cancer-favoring or cancer-producing factor prominent in the one race and not prominent in the other. If white males ceased smoking it is obvious that they would have fewer lip cancers, though even then more lip cancers than colored male smokers have. But, white males having some cancer-producing factor other than the lip-irritation-from-smoking factor and five times as powerful as that factor alone, what is to prevent that other factor from producing cancers elsewhere in the body than on the lip, if the lip-irritation factor is absent, in sufficient numbers to make up for the lip cancers which would have been present if the lip-irritation were present?

Assuming that by abolition of smoking we could abolish all lip cancers, our white male population would only have to furnish 345 extra cancer deaths to make up for the abolished deaths from lip cancer; not a difficult thing among some 30,000,000 male whites, about 6,000,000 of whom are above the age of 40 years and at least 3,000,000 of whom are the smokers who furnished the 345 deaths from cancer of the lip. The 3,000,000 would still have among them something over 30,000,000 chronic irritations left as sites for cancers; and most of these remaining irritations are in places where they cannot be removed and, indeed, are mostly of such a nature that their very existence is unsuspected and unnoticed. I myself have at least fifteen chronic irritations upon my person of which I am aware, any one of which may some day be the site of a cancer. Also I am something of a smoker. Even though removable, I decline to part with all these irritations; I propose to keep on shaving, for example; and wearing glasses. Besides my known fifteen favorable sites for cancer I have an unknown and far greater number inside of me. If I were sure that I lack that other all-powerful cancer-favoring factor mentioned above, no amount of these chronic irritations would give me much of a chance to die from cancer. As it is, my chances are about as good as any other white man's in this country who has not as yet developed a cancer, whether I stop smoking or not and whether or not I remove the fifteen irritations which are removable.

Again, does any one claim (and verify his claim) that non-smoking males die from cancer less often

than males who smoke? They certainly die less often from cancer of the lip, but how about deaths from all cancers? Certainly in this country non-smokers in general die from cancer much oftener than smokers, though they rarely die from cancer of the lip. I refer to cancer deaths among women. Among white women deaths from cancer of the lip are in the proportion of 1 to 1,063 of all cancer deaths; colored women, 1 to 1,340.

It is evident therefore that, in itself, chronic lip-irritation from smoking is almost a prerequisite for the appearance of a cancer of the lip; that, though this prerequisite is present thousands of times, a cancer comparatively rarely avails itself of this opportunity to appear; that, the lip-irritation being present, a white man is five times as likely as a colored man to have a cancer of the lip; that therefore, as between white men and colored men, there is some factor far more important than lip-irritation necessary for the appearance of a cancer of the lip; that there is no evidence that non-smoking white men die from cancer less often than white men who smoke; that white women who, in general, do not smoke at all and therefore rarely die from cancer of the lip, yet die far oftener from cancer in general than men, whether smokers or not; that lip-irritation being absent (thereby precluding the appearance of cancer of the lip), it by no means follows that the total number of deaths from cancer will be reduced. Finally, it is evident that even though all possible chronic irritations were removed there would remain innumerable other chronic irritations as sites for the appearance of cancers.

Let us now return to the quotation given above: "If a man past middle life does not smoke heavily, cares for his teeth, and keeps his mouth clean, he is very much less likely to have cancer than one who does not follow the simple laws of mouth hygiene." Negroes in the United States, especially in the Southern States, as a rule smoke, take no care of their teeth, and pay no attention to any laws of mouth hygiene; yet they have cancer much less frequently than white men in the United States whether or not the white men practise the laws of mouth hygiene and whether or not they smoke. And white men as a rule do clean their teeth, go to the dentist, and otherwise keep their mouths clean to a far greater degree than do Negro men. Death rate per 100,000 population for cancer of buccal cavity:

White males, 5.8 (more or less oral hygiene).
Negro males, 2.2 (practically no oral hygiene).

Frequency of cancer of the buccal cavity evidently has no relation to frequency of buccal irritation as between white males and colored males in the United States. White males have more buccal cancers and more cancers in general than male Negroes. Whites certainly have no more chronic irritations, either buccal or other, than Negroes. Here again it is obvious that for the control of cancer chronic irritation is not the most promising point of attack, but rather some other much more powerful factor of a racial, organic, constitutional nature.

White females in the United States do not as a rule smoke, and they are at least as careful about oral hygiene as white males; and far ahead of all Negroes in this respect; but observe:

Death Rate Per 100,000 *Population from Cancer of Buccal Cavity.*

White males, 5.8 (much smoking; some oral hygiene).
Negro males, 2.2 (much smoking; no oral hygiene).
White females, 1.2 (oral hygiene; no smoking).
Negro females, 1.0 (some smoking; no oral hygiene).

Total Cancer Death Rate Per 100,000 *Population.*

White males, 66.1	White females, 92.0
Negro males, 35.3	Negro females, 83.7

(These figures are approximate only and are for 1914, U. S. Reg. Area. Relatively, however, the figures are accurate, the approximation being the same in each case.)

An attempt to harmonize these two tables on the basis that chronic irritation is a large factor in the numerical incidence of cancer soon brings one into a hopeless snarl. For example, Negro males should have the most buccal cancers. White males beat them 2 to 1. Negresses should have far more buccal cancers than white females. They have fewer. White males have more than four times as many buccal cancers as do white females and more than five times as many as do colored females. Yet the general cancer death rate both of white females and of colored females is far ahead of the white male rate. It is plain that chronic irritation in a given locality has nothing to do with the numerical incidence of cancer in general; that it has an appreciable though very small effect in increasing cancer incidence in its own locality (considering the enormous numbers of such irritations and the relatively few resulting cancers); that even this very small effect is inconstant, extremely variable, and absurdly inconsistent; and that, as before, there is present some other much more important and essential factor—one which disregards chronic irritation in this or that locality and controls the numerical frequency of cancer irrespective of the presence or absence of chronic irritation in any given locality. The most that can be said about chronic irritation in the buccal cavity in this connection is that among white males in the United States it seems to favor the appearance of cancers in the buccal cavity. But that is only a part of the truth, for it is proper to add that among Negroes such cancer-favoring effect is practically negligible; and that relative frequency or infrequency of buccal cancer has apparently no effect at all upon the numerical incidence of cancer in general nor upon the general cancer death rate.

Consider all chronic irritations as a whole. Who is prepared to prove that white females have more such chronic irritations than either white males, colored males, or colored females? Yet white females have cancer oftener than any of the others. Who ventures to say that Negro men have fewer chronic irritations than any of the others? Yet Negro males have fewer cancers than any of the others. Who cares to state that Negresses have more than twice as many chronic irritations as do male Negroes? Negresses have more than twice as many cancers as male Negroes. Who is willing to assert that single white women have more chronic breast irritations than married white women? They have more breast cancers. Who will demonstrate that Jewesses have fewer uterine irritations than Gentile women? They have fewer uterine cancers.

Who will show that uncivilized peoples have only about one-eighth as many chronic irritations as do civilized peoples? They have only about one-eighth as many cancers. Do wild animals in their natural surroundings have no chronic irritations at all? Presumably they do have cancer occasionally, though I have not yet been able to find an authenticated instance of it. Cancer among wild animals is at any rate a great rarity.

I am not claiming that chronic irritations are not the usual sites for the appearance of cancers. They are. For the sake of the argument let it be assumed that chronic irritation is a prerequisite for the appearance of any cancer and of every cancer. Then let us assume that we have removed from every individual in this country every chronic irritation that can by any possibility be removed, and that in no instance has any physical damage been done to any individual. This is an absurd assumption, but it is made to show the utmost possible limit to which cancer control by this method could conceivably go. How much would the cancer death rate be diminished? No one can say, but any one may venture an opinion or a guess.

In each individual of cancer age there would remain, after all possible chronic irritation removals, enough chronic irritations unremoved (because unremovable) to furnish sites for a dozen cancers; each individual would also have from one to a hundred favorable cancer sites to replace the ones removed—scar tissue. Most of these replacement sites would be less favorable sites than the ones removed; but some of them would be more favorable because some chronic irritations are very rarely the sites for cancers—corns, for example. Furthermore, the vast majority of even the most favorable chronic irritation sites for the appearance of cancers escape the distinction of becoming cancer sites in reality. We should have then a population still more than amply supplied with chronic irritations; we should still have as before the vastly more important sex, race, color, age, and civilization factors intact; above all, we should still have in active operation the unknown essential fundamental cause of cancer. We should be in precisely the same position as to cancer incidence that we are at present. The *cancers* would appear in other localities. That's all. That is my opinion—or guess; and as matters stand it is at least as good an opinion or guess as any other. Nor is it pessimism. On the contrary it is optimism to those who, like myself, are firmly convinced that cancer is always, from start to finish, fundamentally a constitutional disorder; but that is another matter. In any case we should be *sure* of the truth before venturing to teach to others as the truth what we merely believe to be the truth.

It is often said that "cancer a constitutional disease" is pessimism and therefore not to be thought of unless absolutely proven; while "cancer at first a local disease" at least offers some hope of controling cancer by present methods thoroughly carried out. Waiving the advisability of declining to consider a possible truth on the ground that, if actually the truth, it would be an unpleasant truth, let us examine the pessimism involved in "cancer a constitutional disease." All constitutional diseases are not utterly hopeless—syphilis, for example, or arteriosclerosis—*provided they are properly treated in the early stages.* We do better with those two diseases by early treatment of a constitutional character than we are doing with cancer by treatment of a local character. We could certainly "cure" a gumma by removing it and we can certainly "cure" *a* cancer by removing it. We certainly can not cure syphilis by removing a gumma; maybe we can not cure cancer by removing *a* cancer. At any rate we haven't had much luck up to date in curing cancer by removing cancers. We certainly can prevent gummata by proper treatment of syphilis long before gummata are possible; maybe we can prevent cancers by treating cancer long before cancers are possible. It is really asking a good deal of our credulity to accept as a fact the statement that a fatal disease *begins* as an utterly abnormal and pathological *growth* of cells which are integral parts of the human organism; that cancer begins as a microscopically small biological misbehavior of a few body cells which mysteriously break away from lawful control of the organism to which they belong and of which they are a part; that this very small mutiny is never in any case subdued; that the whole organism, thus impotent, nevertheless feeds and supports the mutineers, sometimes for months while the mutineers are few in number, so that the mutiny may not die out; that the organism never succeeds in putting a cordon of new connective tissue cells about the rebels so that they shall be confined to the spot where the trouble began, as the organism often does in other kinds of local disturbances which threaten to bring disaster upon the entire organism if not thus controlled; that the organism as a whole devotes its entire energy, not to putting down the mutiny, but to giving it every possible facility to spread and ultimately to kill the organism. This is really asking a good deal.

Just to see how pessimistic would be the outlook, let us assume that cancer is a constitutional disease which begins long before a cancer is possible, and that *a* cancer is possible only because there has been a preceding serious and progressive constitutional disorder which has advanced to a certain point; that this disorder is incurable at any stage but that it may be *arrested* indefinitely at a stage before a cancer can appear and sometimes, though much less often, even after a cancer has appeared but before it has been in existence very long; that after a cancer has appeared the underlying constitutional disorder soon reaches a stage which is sooner or later necessarily fatal to the organism, though the fatal ending may be delayed somewhat by removing every possible unnecessary burden from the struggling organism. Assume that and one has a general idea of what the writer believes cancer to be. On this basis cancer and old age have a good deal in common. As a matter of fact they have a great deal in common on any view of cancer. Cancer is essentially a disease of old age exactly as is arteriosclerosis, which is not a disease at all in old age but a normal phenomenon, while in mid-life it is a disease—premature old age of the arteries. Moreover the death rates from cancer and from arteriosclerosis (apoplexy) in America run precisely parallel courses from mid-life to extreme old age. Old age may be postponed by proper measures until its physiological time; it can not be "cured."

Each disease, premature old age and cancer, is overwhelmingly a disease of modern civilized life, though each occurs to some extent among all peoples.

Assuming that cancer is a constitutional disease in the same sense that premature old age is a constitutional disease and may be controlled by the same means, it is the reverse of pessimistic to think of cancer as a constitutional disease. Moreover, that assumption fits the known cancer facts in a very satisfactory manner. Finally, no possible harm can result from acting upon that assumption even if such action has no anticancer effect; if generally acted upon in America there would certainly be fewer deaths from apoplexy in mid-life.

I venture a prophecy: When the mid-life death rates from arteriosclerosis, apoplexy, "paralysis," chronic nephritis, and organic heart disease are markedly lowered in America, the cancer death rate will simultaneously be markedly lowered—*and not before.*

The writer was honored by being invited to become a member of the American Society for the Control of Cancer. He accepted the invitation and was duly elected though he called attention to the fact that he was not in accord with some of the official pronouncements of the Society. That he was elected upon such a basis shows the good faith of the Society and its willingness to consider other opinions upon cancer than its own official opinions.

This article is presented in the same spirit of good faith. As a friend and humble ally of the Society, the writer "attacks" one of the official statements of the Society. If the statement cannot be justified, it should not be made; if it can be justified, it should be justified. In the interest of truth the writer throws all modesty aside and challenges anyone to verify that statement. It is a matter of fundamental importance in the matter of cancer control.

169 PLYMOUTH AVENUE, SOUTH.

THE MYOCARDIUM AND HEART MURMURS, WITH ILLUSTRATIVE CASE REPORTS.

BY SAMUEL E. EARP, M.S., M.D.,

INDIANAPOLIS, IND.

CLINICAL PROFESSOR OF MEDICINE, INDIANA UNIVERSITY SCHOOL OF MEDICINE.

THE ability of the heart to perform its function is largely dependent upon the myocardium, and hence any disturbance of the heart may usually be traced to this source, though it may be a functional defect of one of its parts which may be most in evidence.

The muscle, like other muscles, is excitable and contractile and it responds to mechanical, electrical, chemical, and thermal stimuli. The principal differences between cardiac and ordinary voluntary muscle, striated muscle, are: (1) The strength of the response of cardiac muscle does not vary with the strength of the stimulus. The cardiac response is "all or nothing." The smallest stimulus is either incapable of causing a contraction, or if the heart contracts, it is a maximum response. (2) Cardiac muscle possesses a long refractory period. (3) The heart is incapable of entering into a condition of tetanus. (4) Cardiac muscle has a long latent period. (5) Cardiac muscle has an inherent tendency to contract rhythmically quite apart from a nervous mechanism. (Lyle's Manual of Physiology.)

Greene speaks of the difference in structure of the cardiac and skeletal muscle fiber and of unstripped muscle, but assigns it a position intermediate between the two varieties. This, of course, calls our attention to the sounds produced by the contraction of the muscle walls of the ventricle, closure of valves, vibration, and pressure of the heart against the chest wall. This refers to the first sound, and with the second we have the closure of the pulmonic and aortic valves and the vibration.

Now, it seems to me that the fact that the coronary vessels, if the least abnormal, affect the heart very perceptibly, should imply that the valves are in a degree affected. It is accepted that the vasomotor fibers modify the rate and we do not know what changes have sometimes taken place in the blood vessels. We do not know the influence of the vasomotor nerves; but the arteries are supplied with these nerves, and nerves with a sympathetic reaction show evidence of a vascoconstriction. And again we see evidence of a decrease in force of the heart and other abnormalities by the lessened patency of the coronary vessels by disease or otherwise, which results in anemia and malnutrition. This has been demonstrated by animal experimentation in which some portion of a vessel has been ligated. It seems reasonable that these factors should give us certain heart sounds that are not necessarily organic, hence may it not be possible that chemical changes take place within the heart substance or through an influence from elsewhere by chemical action? It is as reasonable as the conclusions we draw from the injury done by toxins; yet this we know, the other may need more light. There is much that is not fully understood. It is a question as to the cause of fibrillary contraction, and what is the function of the nerves related to the bundle of His; such things will be found out by the physiologists. So we call to mind other conditions which change the heart's action; they may or may not be pathological, for instance a dilatation from adhesions or an exudate in the pericardium; it may be a product of inflammation, and the heart substance may not escape or the valve may not respond perfectly. Considering the diaphragm and pleura we realize that an abnormality of the structures may and generally does affect the heart.

It is reasonable to conclude that any pathological condition of adjacent structures, whether it be an inflammation or an undue pressure, may retard the heart's action. The vessels of the heart, independent of the changes which take place in the heart substance, may produce certain heart symptoms that may seem to indicate an organic lesion within the heart itself. It is outside influences, that is, some pathology at a remote part of the body, that often jeopardizes the condition of the heart more than a disease of the myocardium itself. Hence, we often fall into error by assigning to the valves that which belongs to other organs; and so far as the symptoms of a valve lesion are concerned, primarily it may not be the heart. We may again call to mind the pleura, diaphragm, and pericardium as factors. Our deductions may be in error unless we study the condition of the organs remote from the heart. Perhaps this is what Dr. Babcock meant when he said, "When you have a suspicion of heart disease, study the body and all its parts in your examination and the heart last."

The auriculoventricular valves are a part of the

heart substance and it is not strange that an overdistended ventricle should cause a regurgitation, no matter whether it be due to toxicity or to undue excitement, and it is not the valves that require our attention so much as the condition of the myocardium. In fact the valves sometimes stand the stress wonderfully well even when there is degeneration of the myocardium. We must bear in mind that atheroma is a very important factor in the pathology of the heart and blood vessels. Any alteration in the myocardium must necessarily cause us to consider the changes in the coronary vessels; not only in these vessels but in adjacent vessels. Moreover if these vessels are defective in any particular the nutrition of the myocardium is lowered in degree and this may be vital.

It would be of the greatest interest to consider the physiology and pathology of the blood in this relation, but the mere suggestion is all that will be done at this time.

Again I desire to call attention to atheroma because of its importance in rendering a vessel incompetent to perform its full duty. Just a word as to the cause as suggested by Wadsworth founded on his own experience. He says that the great majority of atheromatous conditions rest on some long continued digestive disorder and that hyperacidity with its secondary enteritis is responsible for a very large proportion of such conditions. Simple senile changes, such as loss of elasticity, are often added to other conditions so as to render the picture more complex. It is very evident that the myocardium suffers when the arteries which supply the organ are defective. The lesion may be hyperplastic or necrotic and may be caused by the acute infectious diseases, as scarlet fever. Its presence may not be recognized until after convalescence. Prior to this we may note a soft muscle, though we may not recognize the cause, and not infrequently there may be degeneration during a toxemia. On the other hand, it may be a sequel and arteriosclerosis may follow. The toxins are sometimes very active and may cause parenchymatous charges, such as "cloudy swelling," and it is especially here that the infections, including rheumatic fever, play an important role. With this condition of the heart muscle the valves fail to coapt, and there is a mitral murmur, which may disappear when the general disease yields to the proper treatment. Infection may have caused some loss of tone, perhaps some slight dilatation or a relaxation of the muscular structure of the myocardium. To be organic there must be hypertrophy.

It has recently been said by Cornwall (MEDICAL RECORD, Jan. 8, 1921) that auricular fibrillation suggests a severe degree of nutritional disturbance of the auricular musculature and sometimes there may be degenerative changes, but in a large proportion of cases showing an irregular heart beat there is no demonstrable organic disease of the heart and the irregularity is often due to sinus arrhythmia or premature contractions. Arrhythmia means that the function of the myocardium is at fault both in power and tone, but in children it is not necessarily a sign of organic disease. These are the cases that have been cured by physical training recently so successful.

There may be weakening of the walls of the myocardium, an increase in blood pressure, defective nutrition due to defective coronaries, a somewhat retarded pulmonary circulation—then the valves may not coapt, or there may be a soft, not a snappy closure of the valve; we may have thus a mitral murmur without valvular disease and in some cases a cardiac dilatation may occur through neglect, though it cannot always be prevented.

There may be metastatic abscess and necrotic debris in the substance of the myocardium when there will be a valvular murmur without any disease of the valve. This was shown very interestingly by Dr. Kime when he read a paper with chart illustrations at the College Seminar of the Indiana University School of Medicine. It was taken from his army experience and the result of a large number of autopsies conducted by him.

I am mindful of the bacterial invasion of the valves during the infections, including rheumatism; and there is not infrequently an inflamed endocardium with the seat of disturbance at the aortic and mitral valve, following which, if there be scar tissue, there may be the ulcerative type of heart disease.

In a toxic heart there may be some incompetency, the valves close with a velvet-like sound, perhaps transmitted to the left mid-axillary line, or there may be no valvular disease, yet a murmur; in some cases there is good compensation; in such cases treatment may produce a betterment of the disease and hence a better myocardium, and thus the murmur ceases but, if treatment is neglected, the danger-line is likely again to be present. In the order of their importance as regards prognosis and treatment the general disease comes first, the myocardium second, and the murmur third. While the disease is not organic, neglect may eventually make it so. If the disease is rheumatism we must not conclude that a murmur indicates an organic disease without hope of cure, though I confess this was the earlier teaching. I am told that during the war the majority of men pronounced all murmurs organic, the exceptions being the more recent graduates. Butler, writing in the *Journal of the A. M. A.* for December 11, 1920, said this in substance, and asserted that 90 per cent of these murmurs are not organic.

If the murmur is loud, or if there is good compensation, digitalis is not indicated. If the murmur is soft and the heart muscle weak, or there is recognized a malnutrition of the myocardium, we may use small doses of digitalis or its synergists.

In rheumatic fever it is fairly safe to conclude that if a patient is properly treated for ten days and at the end of this time there is no murmur, we have little reason to expect one later.

We do know that at the onset a patient with rheumatism may have a mitral murmur and that it is possible for it to cease under treatment and not appear again; if treatment is stopped too early it may reappear and when treatment is resumed it may again be relieved; but this chance would have been better if treatment had been continued. This is a victory for therapy. To illustrate I will cite two cases observed with me by Doctors L. F. Reifeis and H. M. Kauffman and two sections of the senior class of the Indiana University School of Medicine at my clinic at the Indianapolis City Hospital.

CASE I.—The patient, a colored girl, aged 18, was admitted to the hospital February 6, 1921, with the complaint of an intensely swollen and acutely inflamed left ankle joint giving much pain.

Family History.—Father is living at age of 49 in good health. Mother died at age of 43 from an acute illness. Four brothers and two sisters living and in good health. No brothers or sisters dead. No history of cancer, tuberculosis, heart disease, or nervous diseases in family.

Past Personal History.—Had smallpox at age of 10 and pneumonia at age of 14 with uneventful recoveries. She does not remember having the usual childhood diseases. Began having attacks of tonsillitis at the age of 10 and these continued each winter until she had a tonsillectomy 3 years ago. No sore throat since the operation and no other sickness. No history of any focal infections, including sinus, teeth, gallbladder, appendix, or tubes. Bowels have always been regular. No history of cough or pains in the chest. Pelvic organs negative.

Present Sickness.—Present condition began gradually a month before entering the hospital. The left shoulder gradually became painful and swollen. Three days later the left knee became swollen and tender upon pressure and painful during movement. About one week later the left ankle became swollen and very painful. The shoulder and knee condition lasted about a week and then improved under treatment of an outside physician. The ankle increased in swelling, was tender and painful and this caused her to come to the hospital. Two days later she had a chill. No history of "rheumatic sweats."

Physical Examination.—On admittance to the hospital the left ankle was intensely swollen, red, tender, and very painful. Temperature 100.6°, pulse 100, and respiration 22. Eyes, ears, nose, teeth, and throat negative. No sinus tenderness. Lungs apparently normal unless slight evidence of congestion in location where there was an accentuated pulmonic sound. There was a soft systolic murmur at the mitral area. Heart seemed to lack strength and force, needed support of medication, otherwise so far as could be determined, was normal. Abdomen negative.

Treatment.—Tincture of digitalis ℥x, t.i.d. for a period of five weeks. Ammonium salicylate grs. xx, with the same amount of bicarbonate of sodium, every 3 hours. Methyl salicylate and chloroform liniment were applied to the ankle incased in dry cotton dressing under bandage. An increased quantity of fluids and a soft diet were ordered. Bowels kept open by enemata, calomel, and Dorsey's magnesia solution. Under this treatment the heart became stronger, and the murmur disappeared, but the join swelling and tenderness decreased very gradually.

CASE II.—A. M., female, age 14, came to hospital February 3, 1921. Complained of swelling and pain in knees and ankle joints, pain in right side, and fever.

Family History.—No importance. Indefinite.

Past Personal History. — Pneumonia, tonsillitis, measles, scarlet fever, bronchitis, and typhoid fever.

Present Sickness.—Pain and swelling in both knees and ankles, a pain in right side near midaxillary line. Profuse epistaxis, probably vicarious menstruation.

Physical Examination.—Pain in the intercostal muscles on the right side. Condition of extremities as described. Sorethroat, headache, abdominal pain, probably visceral rheumatism. Profuse epistaxis. Diaphoresis. Tongue coated. Teeth good. Temperature 102.4°, respiration 26, pulse 124. Laboratory findings unimportant. There was a pronounced mitral murmur which was transmitted to the midaxillary line on the left.

Treatment.—Bowels kept open by Dorsey's magnesia solution and calomel. She was given at the outset ammonium salicylate and sodium bicarbonate, each 40 grains, ammonium bromide, 20 grains, tincture of opium 15 minims, and starch water 3 ounces, by the rectum. For regular treatment she was given ammonium salicylate and ammonium bromide, of each 15 grains per orem every 4 hours. The joints were rubbed with oil of wintergreen and vaseline. For gas pains she received 15 minims of Hoffman's anodyne each 3 hours when needed. Argyrol 10 per cent. was applied in the nose twice a day. For pain in the side and abdomen benzyl benzoate 10 minims every 3 hours, later increased to 30 minims. On account of emesis February 24, the sodium salicylate was given every 4 hours and the ammonium was stopped. There was no evidence of any disease of the heart and the mitral murmur disappeared.

On March 11 the sodium salicylate was stopped because of vomiting. March 13 the mitral murmur reappeared and all the symptoms were worse. Sodium salicylate, 15 grains was given each 4 hours and 5 grains acetyl-salicylic acid each 4 hours. On March 16, there were less swelling and pain, no murmur and none since. March 19, no swelling but some soreness. Temperature 100°, pulse and respiration normal.

By actual demonstration it is evident that toxic conditions from any source, certain conditions of the nervous system, imperfect mechanism of the blood supply, pathological or otherwise, acidosis, the acute infectious diseases, including rheumatism, or an infection at a remote part of the body, may produce a condition of the myocardium which is often characterized by murmurs when there is no organic lesion of the valve, and which very frequently will respond to treatment. It is perhaps too much to suggest the possibility of the effect of uric acid. However, one might bear in mind, whether it is reasonable or not, that uric acid is deposited in localities which have the same composition as the valves of the heart and in the form of urate of sodium and the thought occurs whether or not this may produce a defective valve and that relief may be had as in the treatment conditions due to the effect of uric acid that occur elsewhere.

634 OCCIDENTAL BUILDING.

THE ROLE OF THE PROSTATE IN FOCAL INFECTIONS.

BY P. S. PELOUZE, M.D.,

PHILADELPHIA, PA.

FROM THE DEPARTMENT OF UROLOGY, UNIVERSITY OF PENNSYLVANIA.

THE importance of focal infections as the cause of remote disease processes has occupied so much attention, and their eradication has produced such remarkable results, that it is not surprising that the pendulum should swing too far in one direction. All are agreed that thousands of perfectly good teeth have been uselessly sacrificed, and it is obvious that a saner view is being held to-day. The widespread knowledge of the results following the extraction of abscessed teeth in many cases has so centered attention upon dental infections as to have thrown into the shadow the possibility of other locations of a nidus of infection. The recognition of the prostate as a causal focus is in no sense new, and much has been written upon the matter by a few internists and fewer urologists. However, the knowledge is by no means general, and the important points will bear repetition many times. The frequency of such toxic changes being started by a prostatic focus or kept up by one after tooth extractions or tonsillectomies is probably far greater than is at present realized, and is not surprising when one considers that probably 35 per cent. of all men have a chronic prostatitis.

The recognition of such infections does not of necessity belong alone to the specialist, and the technique of their study could be quickly acquired

by anyone having a fair knowledge of microscopy. While the more complete study of the prostate and its secretion consumes considerable time, the most important question, the presence of pus, can be answered in a very few minutes.

Etiology of Prostatitis.—There is a decided impression in the minds of many physicians that prostatitis is essentially a post-gonorrheal condition and does not exist if there has been no antecedent gonorrhea. Nothing could be more erroneous than this, and it should be borne in mind that this organ offers little, if any, more resistance to other infections than do other structures containing such an extent of mucous surface. It is true that the greater number are post-gonorrheal in the sense that the gonococcus, having been once present, has died out and the inflammatory condition has been perpetuated by secondary bacterial invaders upon a previously prepared mucosa. It must also be remembered that, while true gonorrheal prostatitis in the vast majority of cases seems to be a self-limited disease, there are those patients in whom the gonococcus remains, in the absence of proper treatment, for months or years. Though the gonococcus may have died out, the prostate almost invariably continues to harbor an infection of some type, which infection rarely, if ever, spontaneously disappears.

A small number of cases of prostatitis with no gonorrheal history give no antecedent history that seems to enter into the etiology of the prostatic infection. By far the greater number have either had one of the infectious diseases, such as pneumonia, typhoid, or influenza. A great many have had one or more attacks of tonsillitis or some definite dental infection to which the prostatic infection seems secondary.

Diagnosis.—Considering the simplicity of the study of prostatic infections, the clinician is certainly not justified in advising the extraction of doubtful teeth in men until such a study has been made. The same dictum might also be applied to the removal of tonsils in older persons or those of questionable operability from any cause.

The idea that one can by prostatic palpation alone pronounce a prostate free from disease is wrong and has been the cause of overlooking many badly infected prostates. It is certainly never possible by such a procedure to give the prostate a "clear bill of health." The microscope must always be resorted to for the answer.

Under proper precaution the prostatic secretion is very easily obtained for microscopic study without injury to the patient. Certain things must be kept in mind, however, not the least of which is that roughness is about the poorest treatment in the world for diseased tissues, and in these structures is a common cause of abscess formation. The acutely inflamed prostate should never be massaged. The usual causes of the inability to obtain prostatic secretion for study are faulty massage and ignorance of the structure and function of the parts.

Our effort is aimed at pressing secretion from the prostatic acini into the posterior urethra and thence into the anterior urethra. One only has to bear in mind that the posterior urethra is a tube closed at its proximal end by a very weak sphincter (the vesical sphincter) and at its distal end by a strong sphincter (the "cut-off" muscle), and that improper pressure upon the urethra causes its contents to escape in the direction of least resistance, viz., into the bladder. Therefore, it is obviously best to make several strokes along the lateral prostatic lobes parallel to the course of the urethra and, finally, passing the finger well up over the prostate in the midline, to bring it down with a moderate amount of pressure until it reaches the distal end of the prostatic urethra. This, as will be seen, tends to close off the vesical sphincter and forces the fluid through the distal sphincter into the anterior urethra, and by slight pressure upon the bulbar portion it is forced from the meatus urinarius. Carried out in this way, the danger of forcing pus into the seminal vesicles and thence into the epididymi is avoided, as the midline stroking is in the direction of the flow of the ejaculatory ducts and closes them to the urethral contents. By previous sterilization of the glans the expressed secretion can here be collected for culture.

The usual procedure is to place some of the fresh fluid upon a microscopic slide for study. This study includes the search of the fresh specimen for leukocytes and the stained spread for bacteria.

The fresh secretion of the normal prostate shows from two to six leukocytes to the 1/6-inch field, that of the abnormal exhibits almost any number above this with a corresponding diminution of normal elements.

Bacteriology.—The demonstration of the gonococcus in the secretion of the chronically inflamed prostate is of very rare occurrence unless there has been a recent exacerbation of the disease. It, however, happens at times that when one is unable to find the gonococcus in the secretion the patient will return within forty-eight hours with a positively gonorrheal anterior discharge, showing that the urethra found what the microscope failed to reveal. In view of this possibility it is best always to warn the patient that he may have a discharge within the next two days before carrying out a diagnostic prostatic massage. Such recrudescences generally subside very promptly, but are prone to recur from time to time during one's course of treatment. They are a very fortunate find, as they reveal a dormant gonorrheal focus; the most common cause of the perpetuation of gonorrhea.

The bacteria most often found are the staphyloccus, pneumococcus, diphtheroid (the Hoffman type), colon bacillus, and the streptococcus. The streptococcus seems to be rarely present as a post-gonorrheal secondary invader, but to be more common after tonsillar and dental infections. Though a smaller percentage show the streptococcus, a larger proportion of those that do seem to have distant evidences of toxic absorption.

By far the greater number of prostatic secretions show a preponderance of staphylococci. My studies lead me to believe that pure colon bacillus infections are of rare occurrence.

A Common Clinical Observation of Diagnostic Importance.—In many patients suffering from

toxic absorption from a focus of infection in the prostate there occurs a great increase in the symptoms within twelve hours following a prostatic massage. Particularly is this true of the arthritides in which are at times produced extreme pain and a rise in temperature, analogous to a vaccine reaction. This, however, rarely lasts more than twelve to twenty-four hours, after which there is a marked improvement for several days over the condition prior to the massage. After subsequent treatments these patients experience less and less discomfort and even this disappears entirely as they improve.

The treatment of these patients is properly performed massage at intervals of three to four days until the prostatic secretion is almost or entirely pus-free. The addition of an autogenous vaccine is a valuable adjunct to the treatment and at times brings about remarkable results.

It is not uncommon to find that these prostatic cases, from the standpoints of local symptoms and the amount of pus in the secretion, reach a stationary stage beyond which they do not improve under treatment. Cysto-urethroscopy in many of such cases, particularly if there be any burning in the urethra during micturition, will reveal the lymphocystic bodies that I have described as due to tuberculosis elsewhere in the body. (*Journal of Urology*, Vol. 1, No. 4.) If these are found, a careful study should be made for a mildly active tuberculous focus. Whether this is found or not, the patient should be placed upon a more or less rigid antituberculous régime during which no prostatic massage should be carried out. If the general physical condition improves these urethral lesions will spontaneously disappear in from three months to a year, after which it is perfectly safe to massage the prostate.

In cases where these lymphocystic lesions are not found a period of rest from massage of several months will often lead to a markedly improved local condition, and it is then often possible to clear up the residual inflammation by a short course of massage.

As this is not intended for a discourse upon the effects of toxic absorption, but merely to call attention to the frequency with which the prostate contains the causal focus, I shall give briefly the salient points of a few histories.

So far I have not been able to find what the otologists recognize as a toxic deafness due to a prostatic infection, but see no reason why it could not produce such a condition if an abscessed tooth can, as is stated. Toxic iritis from prostatic infection is apparently not rare, and several such cases have come under my attention in my dispensary service at the University Hospital. Nervous and arthritic symptoms are, of course, the most common.

Case I.—A. R., age 41 years. This patient had never had any venereal diseases though he had been treated by me for a prostatic congestion in 1917. In the first part of 1920 he was incapacitated for eleven weeks by a multiple arthritis which subsided after the extraction of seven teeth. In September, 1920, he consulted me, stating that since his arthritis he had had a "neuritis" over his lower costal region characterized by a severe pain coming on about four in the morning and causing him to arise. For a longer period he had had a constant pain in his upper lumbar region.

Prostatic study showed that structure to be large, boggy, and tender and its secretion to contain about 20 per cent. of pus. Prostatic massage was instituted and for a few weeks each seance was followed by generalized joint pains and stiffness lasting several days at first and gradually becoming less until they disappeared altogether. After two weeks of such treatment the costal pains disappeared entirely, and the backache was entirely gone after the sixth week. The patient stated that he felt better than he had for twelve years.

Case II.—G. D., age 28 years. He had had an attack of gonorrhea in 1917 which had been pronounced cured. He first consulted me in November, 1919, for a morning urethral discharge and an arthritis of both knees and both ankles. An *x*-ray of his teeth revealed no abscesses. His prostatic secretion was 75 per cent. pus, and massage twice a week was started. Within a half hour of his massage his joint pains would become greater for the following twenty-four hours, but for the two or three days thereafter he would feel greatly improved. By the end of five weeks of such treatment his pains had entirely disappeared. Shortly after this he went to another physician who entertained him with urethral packings of gauze, sounds, the endoscope, and almost everything that was small enough to get into the urethra. Five months after he left me his pains returned, but he allowed the physician a full year to fulfill his promise of a cure in six weeks. He then discovered a slight despondency and visited me for some sympathy and cheer.

Upon his return he had some swelling and much pain and stiffness in his knees and ankles. This was greatly increased for twenty-four hours after his first prostatic massage, but all pain and stiffness disappeared after his third treatment.

Case III.—R. E., age 45 years. This patient had had gonorrhea at eighteen years and I had treated him for a short time in 1917 for a chronic follicular prostatitis. Early in 1920 he developed an annoying pain in the left arm and shoulder for which his physician had given oral and local treatments for almost a year. He then consulted Dr. Weisenberg, who made a diagnosis of toxice neuritis and referred him back to me for a prostatic study. The arm at this time was acutely painful and he was unable to raise it above his head. The prostate was large and tender and its secretion was practically pure pus. Following his first few treatments he experienced an acute exacerbation of pain lasting about twenty-four hours. At the end of three weeks all pain had entirely disappeared and has not returned, though he still has a large percentage of pus cells in his prostatic secretion.

Case IV.—B. A. N., age 52 years. This man had had recurring attacks of pain and swelling of his knees and ankles during the preceding four years. He denied venereal disease and his teeth and tonsils were negative, as was also his gonococcus fixation test. His prostate was enlarged and its secretion contained much pus. On the night of the day of his study he had two chills and his temperature went from normal to 104°, returning to normal on the following day. His pain and swelling subsided, but an *x*-ray of the knee showed a chronic hypertrophic articular change which probably accounted for his lingering joint stiffness.

Case V.—C. F. C., age 50 years. **This gentleman** developed a multiple arthritis in July, 1919. His pain and disability were such that he was totally incapacitated when I first saw him in December of the same year. The *x*-ray had revealed three abscessed teeth which had been removed without benefit. He was bedridden with greatly swollen, painful knees and ankles and his calf and leg muscles were markedly wasted. His prostate was broad, soft, and flat and its secretion was almost pure pus. Following his first few prostatic massages there was such a great increase in his pains that opiates were necessary. These reactions quickly decreased and after three weeks he was removed to his home free of his constant pain and experiencing only occasional attacks which entirely stopped within six weeks. The joint swelling rather quickly disappeared, though it took some months to regain his

strength and agility. He now weighs thirty pounds more than when he left the hospital, and states he is perfectly well.

CASE VI.—J. H., age 27 years. He had had gonorrhea complicated by a gonorrheal anthritis in November, 1916, which lasted about five months. He then had no difficulty until July, 1919, when his right knee and both ankles became painful and swollen. A short time after this he developed a frequent sharp pain over the lower anterior part of the chest when he breathed deeply. This latter was worse at night. When I first saw him, Feb. 7, 1921, he had lost thirty-five pounds and stated that he had not had a full night's sleep for a year and a half. The right knee and both ankles were swollen, painful, and tender, and both plantar arches were broken down. An *x*-ray of his teeth was negative for dental abscesses. The prostate was small, not tender, and its secretion showed about 75 per cent. of pus. There was a marked increase of his symptoms following the first few treatments, but these soon disappeared. His statement on Feb. 21, 1921, was that his pain was entirely gone and that he was able to sleep all night.

1831 CHESTNUT STREET.

WRITER'S CRAMP: ITS CAUSE AND CURE.

BY W. H. BATES, M.D.,

NEW YORK.

WRITER'S cramp is one of a considerable group of so-called occupational neuroses occurring with more or less frequency among persons whose living depends upon their ability to use their hands rapidly and continuously for many hours a day, such as writers, telegraphers, pianists, violinists, seamstresses, etc. It may affect only one or two muscles, or it may involve the entire hand, or the entire arm and shoulder. The chief symptom is inability to use the hand, or difficulty in using it, for writing or other occupational purposes. Writer's cramp, being the most common of these maladies, is usually treated as representative of the group.

There has been much discussion about the nature of this disease, but it cannot be said that much light has thereby been thrown upon it. About the symptoms the most astonishingly contradictory statements are made, and upon these contradictory observations contradictory theories as to the pathology of the condition are based.

Text-books often state without qualification that the difficulty in using the muscles is confined to the occupational act. Yet it is well known that there are many exceptions to this rule, and most writers state that in the advanced stages of the disease other actions may be affected, or that the occupational cramp may be complicated with other conditions which lead to difficulty in the performance of all finely coördinated actions. A few have reported that the trouble is never confined to the occupational act.

This last was the experience of Poore.[1] "The writer's cramp of the text-books, in which failure of writing power is the sole symptom, I have never seen," he writes, and adds, very significantly: "The conclusion that the patient can do everything but write is often drawn rather hastily from the fact, for example, that he can cut his dinner or play the piano without difficulty. A little consideration will show how widely these acts differ from writing. A dinner-knife is held by flexing the ring and little fingers into the palm, and the first dorsal interosseous if used at all is only called upon for a momentary contraction when the food is being cut. Again, the positions of the hand in writing and piano-playing are quite different. The strain in piano-playing falls upon the extensors of the wrists and fingers and the flexors of the elbows, and it is evident that the momentary contraction necessary for striking the key could be effected by a muscle which might not be able to steady a pen. A patient will often assert that he has no trouble except with writing, because any other trouble he may have is insignificant in the annoyance which it causes him. . . . . There is usually no difficulty in discovering some muscular movement other than writing which is impaired."

In a carefully tabulated report of seventy-five cases involving loss of writing power Poore notes loss of function for other acts in sixty, there being no record in the other fifteen. In one case, the patient, after having at first denied having any trouble except in writing, admitted that in holding a teaspoon his forefinger slipped up the handle, and that he experienced great difficulty in pinning together the two halves of a bank-note. Another had difficulty in moving the regulator of his watch with a penknife. A third could not hold a coin between his thumb and forefinger without a sense of great effort.

Similar observations were made by Ross[2] and Paul.[3] The former says that "in those who suffer from writer's cramp the movements requisite for sewing, pianoforte playing, embroidery, buttoning up the clothes, and all actions requiring delicate manipulation are also impaired." The latter reported to the American Neurological Association in 1911 ten cases of occupational cramp in every one of which the difficulty extended to acts other than those demanded by the occupation.

The idea that the trouble is confined to the occupational act is the foundation of what is known as the central pathology. Duchenne of Boulogne,[4] who was the first to present a comprehensive description of the condition and to attempt an explanation, believed that the difficulty was confined to the occupational act, and noting also that the disease was likely to occur in the left hand after the patient had learned to write with it for the purpose of sparing the right, he argued that the disturbance must result from a morbid state of the brain centers which control the coördination of the muscles used in writing.

This view still prevails, and has been embodied in the name given to these conditions, namely, *occupational neuroses*. "There can be no doubt," says Dana,[5] "that the lesion in typical cases is central and involves the higher reflex centers and indirect motor and sensory paths." Oppenheim[6] postulates "a disturbance of the innervation of the muscles, which occurs only in complicated movements which are acquired by practice, the muscles responding to the will in every other action." Starr[7] regards the condition as a manifestation of a localized neurasthenia. "Any finely coördinated act," he says, "requires the orderly and adjusted contraction of a series of muscles in proper sequence, and this is secured by impulses sent out from the educated set of interrelated nerve centers. If the act is repeated too often, fatigue results. If, in spite of the fatigue, the act is continued, stru-

tural changes in the mechanism underlying it may be caused. These changes may be in the cortical centers of direction; in the subcortical tracts of transmission, *i.e.* the motor tracts, the spinal neurons, or the nerves; or in the muscles. One or all give out under the excessive use." "In writer's cramp," says Stewart,[7] "the patient can use his hand normally for piano-playing or for grasping and using a heavy tool. This is because the weakness is not due to muscular, but to cerebral fatigue."

The smaller number of writers who believe that the trouble is not confined to the occupational act agree in holding to the peripheral pathology. Paul[3] argues for a probable peripheral pathology produced by trauma of peripheral nerve structures, and maintains further that occupation neurosis and occupation neuritis, so-called, are essentially the same in origin, but exhibitions of different degrees of trauma suffered at different loci. Poore[4] says: "I have never seen a case without evidence of a peripheral change, and in the great majority of cases there was no reliable evidence of any pathological change except at the periphera." Beard[9] advanced what he called a compromise view. "This disease," he says, "is primarily a peripheral and local disease of the nerves and muscles; secondarily and rarely it becomes central and general, or it may result from various central lesions; and it may affect any point between the extreme periphery and the center. The theory that writer's cramp is a result of lesion or disturbance of special coördinating centers in the brain is not sustained by a single properly understood fact; on every point it fails to account for and harmonize the phenomena."

In spite of these divergent views about the symptoms and pathology of the disease, all writers agree that the exciting cause is the excessive use of the hand in the occupational activity; but, because this factor is manifestly inadequate to account for it, much importance has been attached to secondary causes. Duchenne laid stress on the importance of mental factors, and this view is now widely held, as it affords a convenient method of accounting for much that would otherwise be unaccountable. Meige[10] puts mental factors in the foreground, holding that in many cases the motor trouble appears very distinctly as a consequence of the mental trouble. He believes that the condition is essentially allied to the tics. Jelliffe[11] says: "Psychoanalysis is of great service for the strictly psychogenic cases, and a great many are such."

There is also a substantial agreement as to the value of rest in the treatment of the condition. "Abstinence from writing, in the writer's cramp form, is the first requisite," says Jelliffe[11]. According to Oppenheim[6] the quickest remedy is "absolute avoidance of the act which brings on the spasm." Starr[7] considers the prognosis good for recovery, "provided a sufficient period of rest can be enforced. This rest must, however, be absolute rest of the function affected," he says. "If it is writer's cramp, the pen or pencil should not be touched or the fingers placed in the writing position for two years." Even writing with the left hand he considers inadvisable, owing to the liability of the disease to develop in that hand after it has appeared in the right. "The wisest counsel one can give," says Meige[10], "is the complete cessation of writing with the hand affected by the cramp." And so one might go on indefinitely.

My own experience with occupational cramps has convinced me that none of the writers whose works are available to me has understood the cause of these troubles. My practice as an ophthalmologist has brought me into contact with a number of persons who were suffering from occupational cramps, and in trying to help one of them, after the neurologist to whom I had sent him had failed, I discovered a remedy so simple that I hesitated to publish it, fearing that my colleagues, as on numerous other occasions, would not believe me. Yet, knowing how general these conditions are, and how disastrously they affect those who suffer from them, I now feel it my duty to do so.

CASE I.—About thirty years ago a court stenographer consulted me about his eyes. He was wearing glasses for myopia, and these, while somewhat helpful, were far from being satisfactory. He became able to see perfectly without his glasses, and was very grateful. A few years later he returned, very much excited and unhappy because he was suffering from writer's cramp and feared that he might be obliged to give up his work.

The trouble was not confined to the writing act, but affected the use of his hand for every purpose. He handled his knife and fork awkwardly, and even shaking hands was a painful ceremony. He had consulted a number of physicians and taken all kinds of treatment, such as electricity, massage, baths, and internal medication, but had obtained no material benefit, and he had now been told that the only thing for him to do was to stop work. He asked me to recommend a nerve specialist, and I sent him to a man who at that time was regarded as the highest authority on diseases of the nervous system in the city. This doctor confirmed the diagnosis of his colleague and prescribed the same remedy, namely, absolute rest until the condition was cured.

The patient returned to me very much discouraged and also much puzzled. He did not understand why he should be told to rest when he worked only ninety days a year and a very few hours at that, while during his long vacations the hand was worse than when he was working. Furthermore, it was always worse in the morning than after he had been at work for a while, and he sometimes had more trouble in the left hand than in the right, though he never tried to write with the former. He had told these things, he said, to the eminent neurologist, but the latter did not seem to attach any importance to them. To me the facts seemed highly significant, and I concluded that the man either did not have writer's cramp or that writer's cramp was not what the books said it was.

"Let us get more facts," I said. "We know what you do with your hands in the daytime. Perhaps it would be a good plan to find out what you do with them in the night."

So he had his wife watch him at night, with the result that he came back a little later and told me that he was cured. It appeared that he had been sleeping with his hands under his head. When this was discovered he tied his hands down at night, but so strong was the inclination to put them under his head that at first he tore them free in his sleep. His wife continued to keep watch over him, however, and saw that pressure on his hands and arms was prevented. Immediately relief followed, and in a week the cure was complete.

Thus it became clear why the cramp had been so much worse in the morning than after the hand had been in use for a time, why the left hand had been affected as well as the right, and why the condition had been worse during vacation than when the patient was working, for in the summer he had spent many daylight hours in the hammock with his hands under his head.

The patient was not only very happy over his cure, but very indignant with the eminent neurologist who had told him that the only remedy lay in giving up his work. He wanted to sue him for damages and show him up in the courts, and it was only by telling him that the object of his animosity had treated thousands of poor people in hospitals and clinics without pay that I was able to persuade him to let the matter drop. The cure was permanent as long as the cause was avoided, and whenever symptoms of a relapse were noticed, prompt relief was obtained by measures which prevented any pressure upon the hands during sleep.

CASE II.—Another case of occupational cramp that came to my attention was that of a telegrapher. She suffered from fatigue and severe pain in her right hand and arm, accompanied at times by inability to do her work, and at such times she had difficulty, not only in manipulating the keys of her instrument, but in using her pen. After rest at night the trouble did not seem to be relieved, but after a few hours' work she was always better. She found that she was sleeping with her right hand under her cheek, and when this habit was corrected the cramp immediately disappeared.

CASE III.—A third case was that of a violinist who was having trouble not only with his eyes but also with his hands. His symptoms were extremely variable. At times he would be all right. At other times he could not play at all. The fatigue varied within wide limits. The pain was also variable both in intensity and location. Sometimes it would be felt only in the fingers, sometimes it would be in one arm and sometimes in the other. Although the fingers of the left hand, which manipulated the strings, were subject to more strain than the bowing or right hand, the pain was sometimes more severe in the right hand than in the left. I suggested to him that his trouble was probably due to his posture in sleep, but he treated the idea as ridiculous, being convinced that he always slept with his arms lying straight by his side and never bent them or put them under his head. I suggested to his wife that she watch him at night, as the wife of the patient previously mentioned had done, and she found him sleeping, first with both hands under his head, and later with his face resting on his hand. He refused to believe this when told, but was convinced when wakened in one of these postures. The same precautions were taken as in CASE I and the cramp quickly disappeared.

I have never known a case of occupational cramp that did not yield to this simple treatment, and in addition to those I have cured myself, many others have been cured by cured patients. The court stenographer told me that he had cured fifty cases, and that many of these patients had cured others."

A SUGGESTION FOR THE TREATMENT OF PELLAGRA.

BY J. W. McCREADY, M.D.,
NEW YORK.

THE successful treatment of gastrointestinal diseases by the use of the chlorine compound, chlorazene, leads me to believe that this drug may be of service in the treatment of pellagra, since it is a disease of "maize" or other poisoning. As chlorazene is not in general use as an internal remedy, I will give a brief history of this chlorine compound.

Chlorazene or para sodium toluene-sulphonchloramide[1] was first made by Chattaway.[2] It was introduced by Dakin[3] as a surgical disinfectant. It is a white crystalline powder with a chlorine-like odor. It was used with great success during the European war in badly infected wounds, irrigation of the bladder and other internal cavities, but I think it is of even more value as an internal remedy. It is decomposed by the secretions of the stomach. This makes its necessary to protect it from the action of the gastric juice while it passes through the stomach. The duodenal juice, rich in bile and pancreatin, decomposes chlorazene slowly, and this liberation of a small quantity of free chlorine causes a prolonged oxidizing action.[4] We know that since the days of Bouchard we have been compelled to utilize feebly soluble disinfectants as intestinal antiseptics, in order that their action may be prolonged during the time necessary for this dissolution; but it is not easy to engage chlorazene in insoluble combination capable of fulfilling this purpose. During my first experiments three years ago, I tried many combinations, both in solution and powder; some appeared to be compatible, but more were incompatible; until at last I decided upon willow charcoal whose power of absorbing various substances is well known. A powder of chlorazene and willow charcoal is inodorous and remains so even after exposure to the air and light for a long time.

In the presence of gastric and duodenal juice, decomposition, with liberation of small amounts of chlorine, does not occur until after two hours. This decomposition continues for twenty-four hours.[5] It was by accident rather than by experiment three years ago that I first used this drug internally, but with such good results that I have ever since used it and I have employed it with charcoal in hundreds of cases as an internal remedy without any ill effects. When given in capsule it may produce a slight burning sensation, but ordinarily patients suffering from gastric or intestinal disorders experience no trouble after the administration of several consecutive doses. Thus, then we may, without fear, prescribe chlorazene in capsules, even for the patient having a sensitive digestive tract. But I would not advise its use in powder form, as it is rather a hot dose to swallow, even with a glass of water, but it can be taken that way if the patient cannot swallow a capsule. My first patient to take the medicine in powder form told me that he was obliged to take as much water as a chaser to get the powder down, as he did with a drink of the poor whisky they are selling to-day; another patient told me she took the powder without any inconvenience in a spoonful of jam, but I would advise the chlorazene and charcoal in capsules or cachets.

I have prescribed it with success in gastric and intestinal diseases, whether acute or chronic. In summer diarrhea and dysentery it promptly disinfects, deordorizes, and diminishes the number of stools. The drug is indicated in ptomaine poisoning and autoinfection; and I have found it to give relief during any such diseases.

The dose is from 1 5 to 3 grains. One third grain with charcoal 10 grains in capsule is a large enough dose in the average case, and should be given not more frequently than every three hours. In gastrointestinal indigestion one capsule after each meal is enough. I am firmly convinced that chlorazene will destroy germs in the intestinal tract, whether there by diarrhea or constipation. When influenza is complicated with intestinal indigestion the drug is indicated and acts well.

Fresh air treatment is another factor which must play an important part in any disease, but I have found that patients will sometimes die of oxygen starvation even in the open, if not given a richer mixture of oxygen than they can get from the air. The air we breathe is at best but one-fifth oxygen and if a patient is very weak from any disease his supply is diminished in proportion to his weakness. There is a respiration beyond the lungs, in fact, the entire body is a respiratory apparatus, and all of the tissues and organs of the body are constantly reaching for oxygen, and if the lungs cannot supply the required amount the tissues of the body begin to grow weak from oxygen insufficiency and at last die from oxygen starvation.

For the past twenty years I have always used oxygen in any disease where there is weakness and depression. As a cardiac tonic there is nothing better (Sir Douglas Powell[5]). The direct effect of its inhalation on the heart is to send more richly oxygenated blood to the left cavities and muscular walls. Oxygen should be used *early* in any disease and not as a measure of last resort. In my opinion oxygen is the most valuable therapeutic agent in medicine. No chemical element enters so extensively into vital processes as oxygen. Its inhalation acts by supplying a deficient necessity of life.

I have had no personal experience in the treatment of pellagra, but from what I have studied of the disease, it appears to be one of the gastrointestinal tract with diarrhea as one of the most important and distressing symptoms.

"Pellagra is the result of chronic poisoning from consumption of spoiled maize, the corn itself containing within itself some toxic principle. So far as I have been able to observe from a considerable experience no drug may be said to exert any decided influence over maize poisoning" (Harris[6]). There is a difference of opinion, however, as to the origin of the disease.

But I know of a certainty that oxygen if given liberally will be of marked value in pellagra or in any other disease where the vital forces are interfered with. As to chlorazene, I can only hope.

My successful treatment of gastrointestinal diseases with this chlorine compound leads me to believe it will be useful also in pellagra.

It is my sincere hope that some of my Southern brethren of the profession will take an active interest in the use of chlorazene and oxygen in pellagra for the relief of suffering humanity.

ACUTE FOLLICULAR TONSILLITIS.

By WALTER W. GRIFFIN, M.D.,

New York.

Assistant Surgeon to the Manhattan Nose and Throat Hospital

The prevalence of acute follicular tonsillitis and its more serious joint and heart complications render its proper treatment very important. But in order to treat this condition it is necessary to understand the exact pathology that takes place during its progress. For this reason the course of the disease should be divided into three stages, (1) Preeruptive, (2) Eruptive, and (3) Convalescent or Contractile.

1. *Pre-eruptive Stage.*—In this stage the germs of infection have gained access to the tonsillar crypts and in their growth have produced toxins and pus causing the tonsil to become inflamed and swollen, but as yet showing no signs of tonsillar spots. However, as the disease progresses, if the tonsils are carefully observed, it will be seen that at the location of the crypts the tonsil is rough and studded very much like the surface of a golf ball. During this stage there has been no drainage from the tonsil and therefore there is the greatest amount of internal absorption of toxins and this is manifested by the severe constitutional symptoms, high fever, malaise, headache, muscular pains, and profound mental depression.

This stage then passes into

2. *Eruptive Stage.*—This is the turning point of the disease. The tonsillar follicles rupture and expel their contents into the mouth, giving the tonsil the typical white-spotted follicular appearance. In this stage if light pressure is made on the body of the tonsil the crypts will exude pus. At this point the toxins are now being discharge from the tonsils and therefore the constitutional symptoms begin to abate; the temperature drops, the malaise and muscular pains lessen, and the patient is decidedly more cheerful.

3. *Contractile Stage.*—After the tonsillar crypts have discharged their purulent contents the contractile stage begins; the tonsillar swelling subsides and the tonsil contracts down to its normal size.

The treatment of acute follicular tonsillitis then should depend on its particular stage when seen.

1. Understanding that the internal absorption is greatest in the pre-eruptive stage and that the tonsillar crypts have not ruptured, our policy should be to (*a*) increase the elimination of toxins and (*b*) promote the early rupture of the follicles.

To accomplish the first the early administration of a large dose of castor oil produces free catharsis and capsules containing quinine bisulphate, salol, and acetphenetidin, given one every four hours will

produce free diaphoresis. Frequent gargling with warm solutions of a mildly alkaline antiseptic will hasten the rupture of the crypts.

2. In the eruptive stage the main endeavor should be to promote drainage from the follicles and to antisepticize them. For this purpose an antiseptic gargle without astringent properties should be used, and the application of strong colloidal silver solutions to the tonsils and within the crypts, if possible, is advisable. The diaphoresis can be stopped. I want to emphasize that in this stage so long as pressure on the tonsil will squeeze out pus from the crypts no astringent gargle should be used, as it serves to shrink up the crypt openings and dam back the pus within the tonsil and force it to seek its way out through a different channel, which often is by breaking through the tonsil capsule and then around either the front or back of the tonsil between tonsil and tonsil pillar, bringing on the familiar peritonsillar abscess or quinsy. I believe many quinsies have been due to too early administration of astringent gargles.

After the spots have left the tonsils, showing that the crypts have thoroughly discharged, we are then ready for the astringent gargle and the best probably is two drams of the tincture of the chloride of iron to the ounce of glycerin, a dram of which to a half glass of water used every two hours will rapidly bring the tonsil to normal size.

The general nursing care, of course, includes alcohol rubs for high temperature.

In conclusion I would add that where the temperature remains up after the advent of the spots for any length of time the physician should be on the lookout for the development of quinsy.

57 WEST SIXTY-NINTH STREET.

Medicolegal Notes.

Relation of Master and Servant Does Not Exist Between Physicians and Surgeons and X-ray Operators Employed by Them.—In an action against physicians and surgeons owning and operating a hospital for *x*-ray burns received during an *x*-ray examination by their operator, the Arkansas Supreme Court holds that the relation of master and servant cannot exist between physicians and surgeons who are not *x*-ray specialists themselves and the x-ray specialist or roentgenologist whom they employ to assist them in the diagnosis and treatment of diseases. The fact that the *x*-ray specialist for whose negligence recovery was sought was working at the hospital in the *x*-ray department equipped by the defendants for such work did not affect the character of employment between the defendants and the operator in this respect. The case seems to have been one of first impression, no case having been found where the exact question has been decided.

The court, after citing the authorities on the history of the *x*-ray, quoted from Witthaus and Becker, vol. 3, p. 799, as follows: "Personal responsibility and liability to a patient for damages caused by the use or misuse of the *x*-ray rest upon the same principles of law as any other branch of medicine or surgery. The same rules, so far as malpractice is concerned, must be applied as laid down in our court of last resort to guide the medical and surgical practitioner. We conclude, therefore," the court said, "that because the science of roentgenology is so interrelated with the sciences of medicine and surgery in the diagnosis and treatment of human diseases, it should be classed in the same category with these sciences. And the *x*-ray specialist or roentgenologist must be placed in the same class with the physician and surgeon because of his peculiar knowledge and technique that he must possess, and because in the practice of his profession such knowledge and technique is dedicated almost exclusively to the aid of the physician and surgeon in the diagnosis and treatment of diseases of the human body. . . . The *x*-ray specialist, or roentgenologist, like the physician and surgeon, unless he expressly contracts to produce certain results, has the right to, and must at all times, act according to his independent judgment and discretion in the exercise of his skill and learning in the treatment of human diseases. The very nature of his profession and the character of his contract of employment involves this right." It was also held that, since the defendants maintained an *x*-ray department at their hospital, it was their duty to exercise ordinary care to see that this department was equipped with such apparatus as was generally approved by roentgenologists as best adapted for the proper diagnosis and treatment of diseases; also to exercise such care to provide competent specialists to do the work in that department. "Ordinary care for the successful management of such institution means a very high degree of care because it has to do with the lives and health of human beings. The *x*-ray machine of the highest type and manipulated by a competent expert is of inestimable value to mankind, but otherwise it is an exceedingly dangerous agency." It was held that the evidence warranted the conclusion that there was no unsafe condition of the screen used by the operator, or that any defect in the screen was not the cause of the injury, but rather negligence of the operator, for which the defendants were not responsible, the operator not being their servant. Judgment for the plaintiff was therefore reversed.—Runyan vs. Goodrum (Ark.), 228 S. W. 397.

Chiropractor Held Competent to Testify as to Extent of Injury to Spine.—In a proceeding under the Illinois Workmen's Compensation Act for an injury to the spine, it was held that a chiropractor, licensed to practice under the Illinois Drugless Healing Act, and who had treated the claimant, was competent to testify as to the extent of the injury. The court said, in part: "Any one who is shown to have special knowledge and skill in diagnosing and treating human ailments is qualified to testify as an expert, if his learning and training show that he is qualified to give an opinion upon the particular question in issue. The injury in question was to the spine. Dr. Fullmer testified that physicians of her school are specially educated and trained to diagnose and treat posterior and lateral derangements and ailments of the spine. That was the character of the ailment suffered by defendant in error. . . . It is not the province of the courts to pass upon the merits of the various systems now in use and practice in the treatment and cure of diseases; but when a physician schooled, educated and trained in any one of these particular systems qualifies as a witness by showing that he has special knowledge or skill in diagnosing and treating the particular ailment or disease which is the subject of investigation by the court, it is the duty of the court to admit his testimony as an expert. The weight of such testimony is to be determined by the character, capacity, skill and opportunty of the witness to know and understand the matters about which he testifies and his state of mind or fairness to the particular litigant."—Voight v. Industrial Commission (Ill.), 130 N. W. 470.

Privileged Communications Under Iowa Statute.—The Iowa Supreme Court holds, in a personal injury case, that complaints made by the plaintiff to a physician who, after the accident, made a surface examination of her in the presence of his office girl, the defendant, and the traffic officer, were privileged under the Iowa Code, Section 4608, although the physician was one employed by the company, where it appeared that he called on the plaintiff afterward in her home and advised her as to a course of treatment. The prohibition of the statute reaches matters learned by observation and examination as well as by verbal communication. The privilege was held not waived by the presence of the defendant and the traffic officer at the surface examination, nor by the plaintiff's admission on cross-examination of having told the physician that she suffered pain.—Walmer-Roberts v. Hennessy (Iowa), 181 N. W. 798.

New York, September 3, 1921.

RECONSTRUCTION OF THE INDUSTRIALLY DISABLED.

A NEW institution has opened its doors at One Hundredth Street and Central Park West, New York, in the building formerly known as the Park Hospital, which furnishes an instructive demonstration of the application of experience and knowledge acquired in the treatment of war disabilities to the great army of the industrially disabled. This is the Reconstruction Hospital, incorporated February 19, 1921, through a consolidation of the Clinic for Functional Reeducation, the Park Hospital, and the Demilt Dispensary, and affiliated with the Institute for Crippled and Disabled Men. The latter was established as a war service for disabled soldiers, sailors, and marines, and from its beginning treated a number of industrial accident cases by the new methods of operation and after-care so remarkably successful in the reconstruction of disabled soldiers.

The primary object of the Reconstruction Hospital is to put the industrial employee injured through accident back "on the firing line" in the shortest possible time and to prevent the seriously injured man from ever becoming discouraged and lapsing into the attitude of the hopeless cripple who so often becomes wholly dependent or a beggar. Surely a worthy aim, and there is no question as to the vast amount of work of this kind waiting to be done. There are in New York State alone 350,000 industrial casualties annually, and the number in the United States each year far outnumbers those disabled in the war. The Reconstruction Hospital will receive patients who have been discharged from general hospitals for after-care or subsequent restorative operation, or it will admit emergency cases immediately after injury. While the patient is still under treatment he is encouraged to continue earning in the occupational therapy department. The patient who is able to work in the daytime may continue his training in the evening classes which are conducted for the partially disabled. When finally discharged, the Institute for Crippled and Disabled Men, through its employment bureau, helps the man to remunerative employment, and if unfit for his original trade he is taught a new one. It is not the aim of the Reconstruction Hospital to have an institution so large that it can care for all accident cases, but to establish a system of treatment and after-care that shall serve as a model for similar institutions throughout the country; to publish researches in new surgical methods; to make a special study of occupational diseases, such as poisoning by lead, anilines, noxious fumes, and to receive and treat all poison cases; and, finally, to train nurses for service in industrial plants. Up to the present time no hospital in the country has engaged in all these activities. A perusal of the list of directors and of the medical staff, headed by Dr. W. Gilman Thompson, whose pioneer work along these lines is well known, bespeaks the success of the undertaking, which initiates a new chapter in industrial medicine. We trust the time is not far distant when facilities such as are offered by this institution may be available to the injured in every industrial center.

The officers of the Reconstruction Hospital announce that they will welcome the opportunity to discuss the services they are prepared to offer with officials of insurance companies, industrial corporations, and others who bear responsibility for the safety and welfare of workers. The financial advantages that would accrue to employers from effective reconstruction work of this kind are so self-evident that they need no exposition or comment.

THE UREMIC SYNDROME.

IN normal circumstances, a diet rich in nitrogenous substances increases the concentration of the urea in the blood, but there is a parallel increase of the ureic excretion in the urine. When the excretion reaches the level of formation of urea in the organism the percentage of urea in the blood ceases to increase and the organism is in nitrogen equilibrium. If the absorption of nitrogen decreases, the urea is at first excreted in a larger amount than is formed until a drop in the percentage of urea in the blood occurs; then the excretion balances up with the formation in order to reestablish nitrogen equilibrium. Kornblum, Achard, and Paisseau have shown that in certain cases of Bright's disease, after absorption of an excess of albuminoids or urea, there follows at first a deficit in the elimination of urea, but the equilibrium finally returns. Consequently, urea does not continually accumulate in the organism. There is a urea content in the blood, an index of ureic retention (Widal) which may vary from one subject to another. For example, an individual having one grain of urea for an absorption of one hundred grams of albuminoids, will present a lower index than a person with Bright's disease who has the same amount of urea for an absorption of only thirty or forty grams of albuminoids per day. Sometimes the urea content of the blood appears normal when there is ureic retention, but speaking in a general way a retention of

fifty centigrams to one gram of urea per liter of blood is bad from the viewpoint of prognosis, but not necessarily fatal, while a retention of one to two grams usually foretells death within a year, and one of more than two grams results in death within a short time. Accumulation of urea can hardly go above five grams and be compatible with life. The same amount of urea is found in the cerebrospinal fluid, and in that of edema, hydrothorax, ascites, etc.

The uremic syndrome is characterized by gastrointestinal disturbances—vomiting, diarrhea, and sometimes buccal and intestinal ulcerations. In the last phase of the process cachexia occurs as a result of the destruction of muscular tissue.

Several procedures have been advised for estimating introgenous retention; Achard and Paisseau's alimentary azoturia test, Ambard and Chabanier's maximum urinary concentration, Widal's index of ureic retention, dosage of urea in the blood or cerebrospinal fluid, and lastly, Ambard's ureosecretory content. But in order that this last test shall be valid the three elements composing it —urea, concentration, and output—must be simultaneously and freely in play. In certain circumstances this condition is not fulfilled, for example, when after a severe diuresis the urea concentration progressively increasing reaches the limit that it cannot go beyond—namely, the maximum concentration. As soon as this is reached, should oliguria persist, and in a sufficient degree, all the urea manufactured cannot be freely eliminated. For instance, suppose a subject is in nitrogenous equilibrium for the usual elimination of one liter of urine; if the elimination becomes less than one liter a certain quantity of urea will be retained in the organism and will tend constantly to increase. Death may take place at this time, but everything may become normal again if a diuresis of over a liter per day can be set up. Therefore, a diuresis cure, as it is called by the French, is the logical therapeutic measure to be adopted as it is the best stimulant of the renal functions and prevents ureic retention.

ACTINOMYCOSIS OF THE MAMMARY REGION.

Actinomycosis of the breast—a parasitic affection —is an infiltration of the gland and celluloadipose atmosphere by the actinomyces. This localization of the process has given rise to considerable study since Kummer and Cumston, in 1892, first described an authentic case. Usually primary in animals, it is rarely so in man, being in most instances a secondary infection. The parasite requires some door by which to enter, either by the galactophorous ducts—which is rare—or by direct wound of the mamma—which is frequent—in which case the actinomycosis is primary. As to secondary infection, it is the result of indirect penetration of the parasite which, having entered by some other channel than the breast, nevertheless reaches the gland, either by tissue continuity or contiguity, which is the most frequent pathogenesis, or by the phenomenon of distant transportation, that is to say, metastasis, which does not take place very frequently.

As to the pathology, the primordial element of the parasitic neoplasia is the actinomycosic nodule. The parasitic lesions do not involve the noble elements of the gland; they infiltrate only the connective tissue of the mammæ, their presence producing phenomena of sclerosis which, by compression, provoke secondary degeneration of the glandular lobules and their excretory ducts. The procedure of staining with iodide-hematoxylin reveals the parasitic grain in the infiltrated tissue and this technique is rapid, easy, and reliable. The evolution of the process takes place in three phases. The first, the onset or neoplastic; the second, one of inflammatory reaction, and the third, one of suppuration. During the first and second phases the diagnosis, although not impossible, is at least extremely difficult, while in the phase of suppuration it is still a matter of considerable delicacy. Nevertheless, it can be clinically established, because microscopical examination of the pus—which should invariably be made—will at once remove all doubt.

Actinomycosis of the mammary gland is a serious affection, requiring immediate treatment. At the onset, when the true nature of the process may be suspected, all forms of iodide treatment may be resorted to. Later on, when medical measures are judged insufficient or when the process has advanced too far, the only rational therapeutic measure is the total extirpation of the diseased breast. And even then, in order to be fully successful, all the infiltrated structures must be also freely excised, going far beyond, both in depth and surface, all suspicious tissue. It is for this reason that it is absolutely necessary to operate at the very earliest possible time, as soon as the diagnosis, in the suppurative phase, has been made, or, better still, at the very onset, as soon as there is the slightest suspicion that the process is actinomycosis, when iodide treatment carefully carried out does not appear to be accomplishing any marked effect on the evolution of the process. It is not necessary to deal surgically with enlarged axillary lymphnodes when these exist. Enlargement of the glands is rare in this lesion of the breast and is not the result of infection by the parasite.

ONCHOCERCOSES.

From time to time abstracts have appeared in the columns of the Medical Record on various superficial manifestations due to filarial embryos or adult filariæ. These vary considerably with the place of incidence, the races attacked, etc., and such differences may in part be due to differences in the parasite. One species of filaria may cause a condition not unlike scabies which is known as craw-craw. Another is instrumental in causing cysts in the integument, while in a third affection erysipelas is closely mimicked. There is a form of

filaria known as *Onchocerca cæcutiens* because it causes blindness, the mechanism of which is not quite apparent. In *La Presse Médicale* for April 6, 1921, xxix, 28, Joyeux, professor of parasitology in the University of Paris, contributes a brief article on a form of onchocercosis encountered in Guatemala which is illustrated with a photograph of two victims. His account harmonizes some of the conflicting statements of authors who have perhaps not been expert parasitologists.

The chief manifestation of this affection is the presence of cysts about the head which contain adult filariæ. With the cysts one sees other lesions including a pseudoerysipelas and affections of the cornea and iris which lead at times to blindness. After a period of three months following exposure, the cysts appear about the head, from one to as many as nineteen, chiefly on the posterior aspect so that the eye usually escapes. Perforation of the skull has been known to result. In the acute type we see an affection much like erysipelas with a temperature as high as 104°. The ears, eyelids, and upper lip become greatly swollen and the resulting picture is characteristic. There may be intense itching or severe neuralgiform pains. In the chronic form the appearance is that of chronic eczema. The ocular lesion is a keratitis, either punctate in the superficial type, which is the rule, or more rarely an interstitial keratitis. This may lead to an iritis and blindness may result after several years, apparently from mechanical causes through the formation of a false membrane. The parasite is the *Onchocerca cæcutiens* of Brumpt and the mode of transmission, presumably through the activities of some insect, is unknown, although the latter is believed to be a simulide. The geographical incidence is very limited which suggests a special insect host.

While the description of the disease as above given is found in the works of Brumpt and other systematic writers, confusion arises from fragmentary accounts of the malady sent home by visiting physicians who describe only what they see or are told. It is evident that most of the superficial lesions of filariasis or rather of onchocercosis coexist in the same subject, the differences pertaining only to the stage and degree of the infection, or to the stage of development of the parasite.

Secondary Diphtheria and Diphtheroid.

An interesting case of nearly apyretic membranous angina, occurring in a young woman, is reported by Achard in the *Bulletin Médical* for May 18-21, 1921, xxxv, 21. The membrane did not have the typical diphtheritic characteristics and the angina proved to be due primarily to the pneumococcus. On the fifth day of the process the appearances were more suspicious, and some true diphtheria bacilli were found in a smear. After an injection of serum the smears contained only pneumococci. The condition appeared to represent a superinfection of a pneumococcus angina with the true diphtheria bacillus. In uncomplicated pneumococcus angina the temperature is usually high and this is also true of mixed infection. The present case is therefore paradoxical, for at no time did the temperature go above 102 Fahr. Both pneumococcus angina and pneumodiphtheritic association are rare and hence too little is known of them. On the other hand, streptodiphtheria association is comparatively common and known to be very serious. Staphylodiphtheritic association is less severe and is said to occur in the course of measles and buccal infections. Fasospirillo-dipththeritic association is sometimes seen—Marfan has observed 20 cases. Of a different nature are the diphtherias which complicate the acute infectious diseases. In scarlatina secondary diphtheria has to be distinguished from the pseudomembranous angina due to the disease itself, which is readily done by examination of smears and cultures. Precocious and severe diphtheria may complicate measles. In both conditions the rule is to inject antitoxin without waiting for the bacteriologist's report. Complications of diphtheria with the other acute infectious diseases are rarely seen, and this is true of bronchitis and pneumonia.

Persistent Thymus.

The significance of persistent thymus is discussed by Yamanoi in the *Schweizerische medizinische Wochenschrift* for June 16, 1921, li, 24. The study is made on the autopsy material of Professor Hedinger's pathological department of Basle University. Of 303 subjects dead of influenza during the pandemic of age period 25 to 50, nearly a fourth presented evidence of persistent thymus, the condition being somewhat more common in the male. While the curves show some irregularities there doubtless would be in a sufficiently large material a steady decrease in frequency with the rise of age. In the author's material there chanced to be more cases at 31 and 27 than at 25, while at the other extreme the incidence at 40 was about the same as at 50. The lowest incidence chanced to be at 43. But the general trend of the figures is unmistakable. No attention is paid to the lymphatic system as a whole. The lower figures in the female are associated with repeated gestation which has a special tendency to hasten involution of the thymus. The state of the thyroid was noted and the gland was found to be enlarged in the majority, about 74 per cent. exhibiting hypertrophy. This frequency could not have been due to the influenza, but was apparently dependent to a greater or less extent on the frequency of endemic goiter in the vicinity. There can be little doubt, however, of a necessary association between persistent thymus and slightly enlarged thyroid.

News of the Week.

May Burn Town to Fight Cholera.—A report from Riga on August 24 announces that a total of 78,011 cases of cholera have been registered in Russia from the beginning of the year to August 10. Conditions in Astrakhan on the Volga are so desperate that local authorities have proposed that the whole population be transferred to Siberia and the town of Astrakhan be then set on fire.

Infantile Paralysis Spreads in New York State.

—New York State Health authorities stated on August 22 that ten cases of infantile paralysis had been reported from Westchester County, thirty-three from Utica, fourteen from Herkimer County, and others in various parts of the State, making a total of 100 cases. Dr. Hermann M. Biggs, State Health Commissioner, expresses the opinion that there is no need for alarm. At the same time he urges parents to keep their children away from large gatherings and advises that children be not permitted to become over-fatigued. During the first eighteen days of August 53 cases of infantile paralysis with eight deaths were reported to the New York City Health Department. Most of the cases have been mild in type. It is thought that they have been brought from out of town.

Yellow Fever at Belize.—A cablegram from Guatemala, under date of August 24, states that yellow fever has been reported at the port of Belize, British Honduras.

No Medicinal Beer.—Secretary of the Treasury Mellon has reversed his attitude with regard to medicinal beer regulations, following the failure of the anti-beer bill to pass Congress. The regulations which would permit the manufacture and sale of real beer on physicians' prescriptions will be held up indefinitely. The reasons for this action have not officially been made public. Legal advisers of the Treasury still maintain that it would be legal to issue the regulations, and have so advised Secretary Mellon.

Physicians Uphold Right to Prescribe.—The Medical Society of Delaware, at its one-hundred and thirty-second annual meeting held in Rehoboth, August 14-16, adopted resolutions vigorously condemning the law restricting the use of alcohol for medicinal purposes. It was the consensus of opinion that practising physicians should be privileged to prescribe any drug they might consider necessary in the treatment of patients. Resolutions were also passed voicing the opposition of the Society to the movement now under way advocating compulsory health insurance.

Child Welfare in Belgium.—A bulletin issued by the Children's Bureau of the United States Bureau of Labor notes that through the second International Conference on the Protection of Childhood, held at Brussels from July 18 to July 21, the attention of the world has been called to the program Belgium is working out for the conservation of childhood. In spite of Belgium's efforts to protect her children during the war, the average child was, at the time of the Armistice, one full year backward in normal development; the weight of the average Brussels school boy was three pounds below normal, and of the average school girl, seven pounds. The first step in the medical reconstruction of industry was the establishment of an independent Labor Medical Service, which includes in its functions the protection of expectant and nursing working women and the care of the health of working children. The service immediately formulated a constructive program which enlisted the cooperation of all agencies concerned in the promotion of public health, including the health of working mothers and their children. In the United States, 18 States provide for the physical examination of every child entering industry, but no State has provided for examinations of working children at regular intervals. Belgium has adopted the advanced program of a medical examination for every juvenile not later than a month after he has entered an industrial occupation, to be repeated once a year until the child reaches 18, and oftener in case of disease. A national children's board has been established, which is maintained by public and private funds, and which supervises and supports child welfare organizations meeting certain conditions. The child welfare program includes the periodical free examination of children under three years of age brought by their mothers for examination; the establishment of free medical dispensaries for expectant mothers; the diffusion of knowledge relating to infant health and maternal nursing; and the supervision of boarded-out children under seven years of age. The cost of child welfare work will be borne one-half by the state, one-fourth by the province, and one-fourth by the municipality. Provincial and municipal boards are appointed by the national board, and advisory committees are provided for.

Ohio Town Chosen for Child Health Experiment.—The town of Mansfield and Richland County, in Ohio, have been chosen by the National Health Council as the scene for the demonstration of what American communities can do in the way of developing the health of their children. Mansfield and Richland County have been chosen because it was felt that conditions there most nearly complied with the qualifications set down by the council for the purpose of securing a typical American community. The demonstration will cover a period of five years and will deal with children of all ages. The objective will be a practical demonstration of what a typical American community can do to increase the health and strength of the next generation. The council hopes to develop a program for child health that shall be so comprehensive and well balanced that it will be of use to other communities all over the country. County and State officers, business men, physicians, and the citizens generally have pledged the heartiest cooperation in carrying out the demonstration. It will be conducted under the direction of Dr. Walter H. Brown, former Health Officer of Bridgeport, Conn., who will relinquish on September 1 his work for the Commission for the Prevention of Tuberculosis in France, and return home to assume his new duties. The national Child Health Council which is directing this work is composed of the following organizations:—American Child Hygiene Association, American Red Cross, Child Health Organization of America, National Child Labor Committee, National Organization for Public Health Nurseries and the National Tuberculosis Association.

Red Cross Publishes Pamphlet on Hygiene.—The League of Red Cross Societies has recently published a pamphlet entitled "Elements of Hygiene," which it is offering for sale in quantities throughout the World. The pamphlet has been copied from the booklet of the Commission for the Prevention of Tuberculosis in France, which was originally published in French. It has now been published by the League in Czech, English, French, German, Italian, Portuguese, Rou-

manian, Serbian, and Spanish. The Red Cross has distributed about three hundred sample copies in this country. The pamphlet contains thirty-two pages and many colored illustrations of the various health maxims it sets forth. For the description of the work of the League may be substituted a description of the organization that may purchase or issue the pamphlet. Further information with reference to obtaining the pamphlets in quantity may be obtained from the Department of Health Service, American Red Cross, Washington, D. C.

Suicides Increase in Germany.—Of the persons who committed suicide in Germany before the war one-third were women. During the war exactly as many women as men took their own lives, that total for both being 8,000. In 1919 the number of men who committed suicide increased to 7,000, while the number of women was again 4,000. There were considerably fewer suicides in the Catholic southern regions than in other parts of the country.

Dr. Russell Stewart Wingfield of Richmond, Va., medical head of the Red Cross unit in Salonica, Greece, who was seriously burned on the night of August 15 in a fire in the Red Cross Child Health Clinic in Kalmaria Park, died of his injuries on August 20.

Dr. George O'Hanlon, medical superintendent of Bellevue Hospital, New York, and Dr. John W. Perilli, member of the Board of Trustees, have been made Chevaliers of the Crown of Italy by T. F. Bernhardi, the Italian Consul General, the decorations having authorized in recognition of their work in the reorganization of the Italian Hospital at Eighty-third Street and East River, New York City.

Vacancies for Roentgenologists.—The United States Civil Service Commission announces open competitive examinations for the positions of roentgenologist at a salary of $200 to $250 a month; associated roentgenologist, at $130 to $180 a month; assistant roentgenologist at $90 to $130 a month, and junior roentgenologist, at $70 to $90 a month. Vacancies in positions requiring similar qualifications may be filled from these examinations. In addition to the salary appointees will be allowed quarters and subsistence when there are available. Applicants for the position of roentegenologist must have been graduated from a recognized medical college with the degree M. D., and have had at least three years experience as a roentgenologist, including *x*-ray physics, technology, photography interpretation and localization. Applicants for the other positions must have completed the eight grades of common school or an equivalent education and have received a certificate of proficiency from or establish equivalent schooling in a recognized hospital, medical college or technical institution in *x*-ray, physics, and technology. For further information applicants should apply at once for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C.

The London Medical Exhibition will be held at the Central Hall, Westminster, London, October 3-7, 1921. The *British and Colonial Druggist* is the organizer, and announces that any physician, surgeon, or dentist from this country, on presentation of his professional card, will be cordially welcomed.

Obituary Notes.—Dr. SAMUEL P. LONGSTREET, of Scranton, Pa., a graduate of New York University Medical School in 1885, died of heart disease on August 16, at the age of fifty-nine years.

Dr. ALICE BURRITT of Washington, D. C., died in a local hospital, July 6, at the age of seventy-nine years. She was a graduate of the New York Medical College and Hospital for Women in 1879.

Dr. WILLIAM J. GALLIVAN of Boston, Director of the Division of Tuberculosis of the Massachusetts Department of Health, died suddenly on July 13 at the age of fifty-six years. He was graduated from Harvard Medical School in 1892 and was formerly City Health Commissioner of Boston.

Dr. JOHN CALVIN WOOD of Portland, Ore., a graduate of the Medical College of Indiana in 1879, died on June 28 at the age of seventy-nine years.

Dr. GEORGE H. ASTLER of Elmwood Place, Ohio, a graduate of the Cincinnati College of Medicine and Surgery in 1890, died of heart disease, on July 7, at the age of fifty-four years.

Dr. HENRY HERMAN of New York City died of heart disease at his summer home at Long Branch, on July 12, at the age of sixty years. He was graduated from Bellevue Hospital Medical College in 1883, and was the first president of the Bellevue Alumni Association.

Dr. FREDERICK N. BEARDSLEY, formerly of Manchester, N. H., died at the home of a relative in Rye, N. Y., on July 8, at the age of forty-six years. He was a graduate of Boston University and during the war was surgeon on one of the White Star steamships.

Dr. ROBERT GUTHRIE, a recent graduate of the Medical Department of the University of Colorado, died at his home in Denver at the age of twenty-seven years.

Dr. HARRY L. ARNOLD of Omaha, Neb., died suddenly on July 8 at the age of fifty-one years. He was a graduate of the Chicago College of Medicine and was on the staff of Creighton University and St. Joseph's Hospital.

Dr. FRANCIS J. DAVIGNON of Ausable Forks, N. Y., a graduate of the Louisville College of Medicine in 1874, died suddenly on July 9 at the age of seventy years.

Dr. HELEN WILLISTON BROWN of New York City, a graduate of Johns Hopkins Medical College and Hospital in 1907, died on July 29 at the age of thirty-eight years.

Dr. ROBERT MATHEWS ULLRICH of Brooklyn, a graduate of Long Island College Hospital in 1904 and a member of the staff at the Ridgewood Hospital, died in that institution on July 27 at the age of forty-six years.

Dr. MAURICE DOREWITZ of Black Rock, N. Y., died of cerebrospinal meningitis in a Buffalo Hospital on July 9 at the age of twenty-six years. He was graduated from the University of Illinois in 1919.

Dr. EINDRED VIKO, a graduate of the Minnesota Hospital and College of Medicine, Minneapolis, in 1887, died at his home in Salt Lake City, Utah, July 12, at the age of fifty-seven years.

Dr. ROBERT MACLEAN TAFT of New York, died suddenly of heart disease on August 8, at the age of forty-seven years. He was graduated from New York University Medical College in 1894. He was a surgeon of the White Star Steamship Line and

during the war served in the British and American navies.

Dr. ARTHUR P. COLL, a graduate of the College of Physicians and Surgeons, New York, in 1889, and a member of the New York Academy of Medicine, died at his home in New York City on August 10, at the age of fifty-seven years.

Dr. JOHN S. GREEN, Sr. of Hagerstown, Md., a graduate of the University of Maryland College of Maryland, 1882, died on August 2, at the age of sixty-four years.

Dr. CHARLES EASTWICK SMITH of St. Paul, Minn., died after a lingering illness on July 23, at the age of thirty-nine years. He was graduated from the University of Pennsylvania School of Medicine in 1908, and in 1919 was appointed secretary of the Minnesota State Board of Health.

Dr. PATRICK J. HIRST, Superintendent of the Herkimer County Tuberculosis Sanatorium at Salisbury Center, N. Y., died suddenly on August 8, at the age of thirty-seven years. He was graduated from the Albany Medical College in 1910.

Dr. J. A. COZBY of Axle, Texas, a graduate of the Kentucky School of Medicine, Louisville in 1884, died suddenly of apoplexy on July 30, at the age of sixty years.

Dr. JOHN P. SHELBY of Yuma, Ariz., a graduate of Jenner Medical College, Chicago, in 1904, died suddenly in Venice, Calif., on July 24, at the age of sixty-three years.

Dr. GEORGE H. BURGIN of Germantown, Pa., a graduate of the University of Pennsylvania School of Medicine in 1884, and for eleven years physician to the Germantown Almshouse, died July 31, at the age of sixty-seven years.

Correspondence.

"AN UNUSUAL CASE OF MALIGNANCY."

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In your issue of July 16 there was reported a case of cancer which was thought to be unusual, and is worthy of comment.

The malignancy affected the left breast of a woman 59 years old, 14 years after the removal of the right breast for a tumor, in 1905. This first tumor had begun in what was called a wen, in 1898, being about the size of a hen's egg, superficial and freely movable; it gave no subjective symptoms until 1905, when it suddenly became somewhat larger and painful, and the breast was removed by a "simple operation." She had had triplets at 31 years of age, in 1891, and in 1897 a daughter was born, who is still living and in good health. Early in this latter pregnancy a double mammary inflammation was developed, with suppuration which lasted for several weeks. The recovery from the operation in 1905, at the age of 45, was rapid and complete. The operating surgeon assured the daughters that the lesion was benign, but the nurse long afterward, that is, very recently, declared that at the time of the operation the doctor had stated that it was unquestionably cancerous: there was probably no pathological examination.

The patient "had been in apparently splendid health" during the 14 years after the first operation, until April 27, 1919, when it was noticed that the left breast was "rather hard and painful, in and about the nipple"; this was regarded as acute mastitis and so treated. As there was no change in two weeks another surgeon performed a radical operation on May 12. The report upon the specimen from the Army Medical School was: "There is no tissue anywhere in all the specimen which can be recognized either macro- or microscopically as breast tissue," and the diagnosis given was "metastatic carcinoma in lymph glands, fat, and muscle tissue." The patient was discharged from the hospital on May 31, the incision being slow to heal in the upper arm. *X*-ray examination showed "no evidence of abnormality of heart, great vessels, lungs, nor of the mediastinum." She then had four adequate radium treatments, at 10 days, 18 days, and 28 days intervals, in the Howard Kelly Hospital, but the left chest had gradually become quite hard, swollen, and painful. She then received morphine in gradually increasing doses, "suffering the agonies of death many times over," until she died June 15, 1920, thirteen months after the operation.

The reporter questions (1) As to the heredity of the disease, her mother having died at 65, from cerebral carcinoma, and a maternal aunt at 68 from cancer of the liver. (Her father died at 70 from tuberculosis laryngitis, and two brothers from pulmonary tuberculosis.) (2) As to the relation of the abscessed breasts to the cancer. (3) Whether the original tumor of the right breast was malignant, considering the good result of the operation, and the 14 years of excellent health before the left breast was attacked. (4) He regards the case of interest, "along with many others on record, as showing how futile, if not worse than worthless, both surgery and radium are sometimes in dealing with early malignancy."

While the case is interesting and worthy of record, it is not an unusual one to those of us who have long seen much cancer. It well illustrates the position the profession has been in, through ignorance or a wrong conception of the true nature of carcinoma, but its features are readily understood in the light of our present knowledge and experience. Referring to the four points made by the writer of the article, we may say:

1. As to heredity. All the best authorities agree that cancer is not hereditary, and in this instance the mother's death at 65 from claimed cerebral carcinoma may have been a mistaken diagnosis, as also that of a maternal aunt from cancer of the liver. Moreover her father and two brothers died of tuberculosis: cancer and tuberculosis are in a measure antagonistic.

2. The previously abscessed breasts had undoubtedly relations both with the first innocent tumor of the right breast, and certainly with the cancer in the left breast, as it is pretty well acknowledged that mastitis commonly precedes cancer.

3. The tumor of the right breast was possibly only chronic mastitis, in which a cystic adenoma developed, wholly benign: it "was and remained a long time about the size of a hen's egg, superficial and readily movable. It gave no subjective symptoms for seven years, until 1905, when it suddenly became somewhat larger and painful"; possibly from some local injury or pressure, and its removal surgically was naturally not followed by recurrence in 14

years. The "apparently splendid health" which she enjoyed during these 14 years is what we continually see in cancer, when it is so hard to convince a patient that the malignant disease has already started. This is not the place to discuss the basic cause of the cancerous local lesion, which has been abundantly elaborated elsewhere, but all agree that cancer may, and most often does, develop in those in seeming perfect health, and we all know that the cancerous cachexia and loss of weight come later.

4. The reporter's comment that the case shows "how futile, if not worse than worthless, both surgery and radium are sometimes in dealing with early malignancy," certainly meets a cordial response in the minds of those who have much to do with cancer. For, attacking only the local manifestations of the disease, carcinosis, they cannot be expected to effect a permanent cure. All of us have seen plenty of cases where they have been employed at the earliest moment possible, even instantly after the discovery of a tumor, and yet the disease has recurred promptly, and the patient died in relatively few months; this patient died 13 months after the operation in spite of four very efficient courses of radium, in skilled hands. Perfect dietary, hygienic, and medicinal treatment yields very different results.

The explanation of the occurrence of cancer in the left breast is very simple: it certainly was not a recurrence, as the lesion in the right breast, 14 years previously, was not cancer (although many of us have seen recurrences fully 14 years after the excision of true carcinoma). The trouble in the left breast was simply a newly developed, very acute carcinoma, or the local manifestation of the carcinosis habit or condition, which had arisen from causes and conditions which have been abundantly elaborated elsewhere. The "apparently splendid health" was only an erroneous expression of the faulty hypernutrition, connected with the deranged metabolism which we so frequently see before the formation of a malignant neoplasm, and the carcinomatous mass is only a mutiny or rebellion of a certain group of body cells against the conditions of disturbed nutriment, etc., in which they find themselves. The reason for the particular local manifestation of the disease in the breast was the damage to the tissues connected with the previous mastitis, as chronic irritation is recognized as the local exciting cause which determines the site of the lesion, although we may not always be able to recognize its nature.

TREATMENT OF FRACTURE OF THE NECK OF THE FEMUR.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD for July 23, 1921, I note the kindly criticism by Dr. Royal Whitman of my article on Fractures published in your issue of July 9th. May I be permitted space for a reply? Doctor Whitman says: "the abduction treatment, which the writer evidently has in mind, is applied under anesthesia and therefore during muscular relaxation. The 'fulcrum' is not the adductor muscles, but the capsule of the joint."

Under general inhalation anesthesia, there is no relaxation of the muscles unless free from irritation or stimulation. Unless the muscles are blocked off by local anesthesia they are very active. The capsule of the joint is made up of white fibrous tissue and has no power of contraction, and could not in a relaxed condition have any power whatever. It is so constructed as to permit of abduction, adduction, flexion and extension, and rotation, without power to modify any abnormal action about the hip joint. Therefore it is not a factor in fractures about the neck of the femur, unless it adds to the disability by being ruptured. The adductors act very powerfully as well as the gluteals in producing shortening, and if they are put on the stretch, as in abduction of the extremity, invariably produce deformity and overriding in cases of fracture of the neck of the femur.

With the shape of the lower extremity diminishing from above downward, and the loose muscular envelopment of the bones, it is an indisputable fact that no plaster of Paris dressing is going to retain the limb in extension after traction has been released by the hands of the assistant, or the Hawley table, or any other device.

We do not have "end-to-end" apposition in fracture of the neck of the femur. This is so apparent as to require no further discussion. We do have a rotary displacement to consider, as made plain in my article, which condition Doctor Whitman seems to have completely overlooked.

Anesthesia has caused the death of many thousands of patients in fracture of the neck of the these cases by use of weight and pulley in the handling of these cases. The proper dressing of these cases by use of weight and pulley in the *straight position*, with sand bags, *and a small sand bag behind the trochanter* is neither dangerous nor painful and is effective. It can be applied by any *intelligent* doctor anywhere on earth with excellent results.

THE VALUE OF A CORRESPONDENCE COURSE IN MEDICAL EDUCATION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—While the correspondence course method of medical education may have its defects, there is no doubt but that the series on narcotic addiction conducted in your columns has been productive of valuable educational features and results not yet attained in the usual formal methods of committee and official report and announcement.

It has brought out some very interesting and useful information of which the profession as a whole has been ignorant. One is that all of our late "muddle" and squabble over narcotic laws was "barking up the wrong tree." From the contributions of Judge Collins and Dr. Rooney we find that the State law was administered through rules and regulations which produced effects exactly opposite to those intended by the makers of the law. In other words for the last year or two we have been governed through administrative authority and power by the Cotillo and Fearon-Smith bill type

of administration under a statute devised and planned after long experience and investigation and study to operate to the opposite effect. So that in final taking account of stock, the failure of administrative experiment and whatever of the present situation is attributable to such failure must be charged up to the ideas behind the Fearon-Smith and Cotillo bills. As Judge Collins stated, the situation was due to "enforcement of promulgated rules and regulations which were in some instances tantamount to repeal of the law and contrary to its intents and purposes." No wonder the profession got confused, with one law on the statute books and its rejected opponent actually in effect. If the correspondence course has done nothing else it has at least cleared up this important matter of which the profession was generally ignorant, namely, that with one law on the statute books they were actually being governed by another that had been rejected by the Legislature.

There are several very important things which have been brought out, but space is lacking for their discussion. One of them, however, is too important to be overlooked and that is the extent to which personal controversy has entered into and obstructed and obscured the medical and scientific issues and needs of the situation. Calling people names and loosely attributing ulterior motives may be for some an entertaining form of literary diversion, but it is never going to solve a complex situation or problem. If the revelation of the existence of these things in your correspondence course brings about their cessation, the profession will have something to thank that course for, and can get down to the needed work on the real issues of the situation.

In this connection I would call attention to a clarifying editorial article in the Bulletin of the Chicago Medical Society for August 20, which has just come to hand, showing how one medical organization is trying to get to the bottom of some of the real difficulties of the situation. I do not know who the writer of the article is, but he certainly has a firm grip of the situation and deserves the thanks of his colleagues as well as of the innocent sufferers from drug addiction disease for his clear presentation of the subject.

In the latest contribution to your correspondence series Dr. Mabbott introduces the therapeutic aspect of the situation, in his reference to compelling the victim of drug addiction to avail himself of "modern treatment for cure." A contribution on the subject of "modern treatment" would be a valuable subject for further discussion. Dr. Mabbott's reference to the matter arouses curiosity and hope that he may add something to our present knowledge of the subject by explaining just what therapeutic procedure he refers to as "modern treatment for cure," including of course what his conception and definition of the "cure," of this condition may be. There are hundreds of thousands of suffering people vitally interested in this subject as well as many physicians. We would all be interested to know just what "modern treatment for cure" he has reference to, and where it can be obtained.

ERNEST S. BISHOP, M.D.

NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, August 11, 1921.

London Preventive Work in Venereal Diseases.—A report on the London County Council's work in connection with the diagnosis and treatment of venereal diseases has been issued recently. The joint scheme for London and the counties in the vicinity of London commonly known as the Home Counties, has been in operation now for four years and it was agreed some little time ago after consultation with Sir George Newman, the Chief Medical Adviser of the Ministry of Health, that a representative of the Ministry, Brevet-Colonel L. W. Harrison, D.S.O., M.B., and Dr. F. N. K. Menzies, on behalf of the Council, should carry out a joint inspection of the hospital clinics and hostels at which the work is being carried on, and the report now published is the result of that joint inquiry. The report stated that there are probably 100 or more refuges and rescue homes in London, managed and financed by the Church of England, the Church of Rome, the Church Army, the Salvation Army, the Wesleyans, the Young Women's Christian Association, the Jewish Community and others. Discussing various general questions in connection with the causes and spread of prostitution, the report says as follows: "With the close of the war there came a gradual cessation of munition making and other war work, with the result that many girls unable to earn the high wages they had become accustomed to, went on the streets either to supplement their smaller earnings in other work, or because they said they had no other opportunity to earn money. According to the testimony of many reliable rescue workers, a very large percentage of these girls are quite young, 16-20, and suffering from venereal disease. It is important to draw attention to the universally expressed desire amongst rescue workers for the provision of what may be conveniently termed 'reception houses.' The women police, police-court missionaries, Young Women's Christian Association, and other rescue workers bear emphatic testimony to the fact that such houses are the overwhelming need of the moment in connection with rescue work. To understand the importance of the 'reception house' to the rescue work it is necessary first of all to grasp firmly the fact that to be able to seize and take full advantage of the 'psychological moment' is an essential factor for successful rescue and preventive work."

The report goes on to say that it is impossible for anyone to study venereal disease day after day without the question constantly recurring in the mind, "Why do women prostitute themselves?" When one sees quite young girls of 13, 14, 15, and 16 years old appearing as patients suffering from syphilis or gonorrhea or both, and boys and young men suffering similarly, it is natural to inquire into the circumstances which led to their infection, and to wonder why so much attention is being given to treatment and so little, comparatively speaking, to causation. Undeniably prostitution is the outstanding factor in the causation of venereal disease, and the Great War must have drawn the attention of all thinking persons to its wide prevalence, as also to its very serious effects in a hundred ways upon

the health of the British Navy, Army, and Air Forces, as well as on the community generally. All who have any knowledge of the history of venereal diseases know that the number of cases has always increased rapidly during and after a war, and this has been the experience in London and in Great Britain generally during recent years, as it has been the experience of all other countries involved in the war just over. Beyond question increase of prostitution in one or other of its many forms, professional, clandestine, etc., has been the cause of this increase in venereal disease. Among the conditions in normal peace times which lead to prostitution, the report mentions: bad housing, bad companions, temperament, drink, homelessness, unhappy homes, seduction and desertion, compulsion and exploitation, feeblemindedness. In regard to temperament, it is observed: rescue workers state frequently that "the girls who come to us at the present day are largely of an emotional temperament, and they are often artistic, musical, good-natured, and very lovable." "The strong, hard-working woman who used to come to us is a thing of the past and has been replaced by the better educated, but also weak-minded, pleasure-loving girl, unable to battle with the difficulties of life." On the other hand, other workers of many years' experience say that "the modern prostitute is more temperate, more cautious, more thrifty, and less hysterical than the prostitute of thirty years ago."

As for the influence of drink on the prevalence of prostitution the report states that it is generally thought by those of long experience in rescue work to play little part in inducing the young to choose prostitution as a career, though it is used by those who desire to seduce a girl to overcome her first resistance, and there can be no doubt that in many cases seduction is the determining factor which leads to a life of prostitution. The question is dealt with at some length from its economic aspect. According to the report, it has been said frequently that prostitution is not an economic question. There are others who hold that this view is entirely erroneous. There is a mass of evidence going to show that unemployment, low wages, and bad occupational conditions are definitely associated with prostitution. In the case of unemployment it has been shown that, in what are known as the seasonal trades, there are many workers who take to the streets to tide over the slack times. Examples of such trades are millinery, dressmaking, tailoring, and the lower ranks of the theatrical and musical hall profession. In all these trades good clothes and a smart appearance are necessary for the effective seeking of a new engagement. Low wages, not necessarily so low as to preclude the provision of food, clothing, and shelter, but without curtailing the necessaries of life, have certainly been shown to be a factor tending in the direction of prostitution. Wages on a subsistence level give very little protection to certain temperaments from the temptation to buy with the proceeds of prostitution the pleasures so much sought after. Occupational conditions, in the opinion of the compilers of the report, form an important influence in leading women into prostitution. This is especially the case where girls are liable to suffer when dependent upon the pleasure of a person of the opposite sex for the opportunity to gain a livelihood, or again, to obtain promotion in their work to positions with higher remuneration. These factors have been shown frequently to be an influence in the case of shop girls, factory girls, theatrical and music hall artists. The fact that domestic servants provide such a large proportion of known prostitutes is certainly not due to low wages or unemployment. On detailed inquiry it will probably be found that it is a comparatively rare event for intelligent, well-educated domestic servants living with families under reasonably good circumstances to become prostitutes, and the truth is that in the vast majority of cases the domestic servant who becomes a prostitute is feebleminded, and for this reason also is occupied in service in poorer families, boarding houses, hotels, restaurants, and other places where the risks of seduction, etc., already referred to, are common.

The main feature of this report is the emphasis laid on the importance of preventive and rescue work. Also parts of the report are valuable from the standpoint of the social and economic aspects of the problem.

Progress of Medical Science.

1. Pneumonia in Infants and Children. A Clinical Study of 208 Hospital Cases. Arthur Bates Lyon.
2. Eczema in the Breast Fed Baby, and Protein Sensitization. Edward Scott O'Keefe.
3. Significant Reactions of the Arterial Tension. Manifestations of the Angio-Kinetic Energy Clinically Observed and Interpreted. Claës Julius Enebuske.

1. Pneumonia in Infants and Children. A Clinical Study of 208 Hospital Cases.—Arthur Bates Lyon analyses this series of cases, occurring in patients 12 years of age or younger, admitted to the Special Service for the care of acute respiratory infections at the Boston City Hospital from February 3, 1919, to February 1, 1921. Of the 208 cases, 109 were of the lobar and 99 of the lobular type. The total death rate in the lobar pneumonias was 4.6 per cent., but in uncomplicated cases, it was only 1.9 per cent. The total death rate in bronchopneumonias was 35.1 per cent.; 74.3 per cent. of these deaths were in patients two years of age or younger. The clinical behavior of both groups parallels in general that recorded by other observers.

2 Eczema in the Breast Fed Baby, and Protein Sensitization—Edward Scott O'Keefe finds that a large percentage of breast fed infants suffering from eczema show a positive cutaneous reaction to food proteins. Of 41 cases tested by the writer, 25, or 61 per cent., showed a positive reaction to some one or more of the proteins used. Foreign proteins occurring in breast milk are the most probable means of sensitization in this group of cases. Egg and cows' milk proteins give the most frequent responses to cutaneous tests in the eczema of older children. Apparent cure in about 40 per cent. of these cases, and definite improvement in about 20 per cent. more of the cases, has followed the omission or limitation in the maternal diet of one or more food proteins to which the infant is sensitive.

12. Chronic Effects of War Gassing. Z. I. Sabshin.

1. The Predisposing Factor in Diphtheria.—Bela Schick argues that it is justifiable to make use of experimental findings in the interpretation of clinical phenomena, and on this basis it may be concluded that the function of antitoxin formation in diphtheria varies in different individuals both with regard to speed and quantity. We may assume that the morbid processes reach their climax and commence to decline as soon as antitoxin appears in the circulation, for from this moment newly formed toxin will be neutralized. It is, therefore, clear that the symptoms of an infection of a given virulence will be milder the greater the speed and abundance of antitoxin formation Thus, the most severe manifestations will be encountered in those individuals who are unable to produce it altogether or only after a long delay. In practice children are found to exhibit all grades of reaction between the two extremes. The mildest cases may be expected who did in fact have traces of antitoxin before the onset of the illness, though the amount in circulation was too small to be detected clinically and insufficient to prevent infection. Such children would be especially adapted to react to the stimulus of circulating antitoxins by producing the necessary quantity of antibodies in the shortest space of time. Thus the conclusion is reached that, in addition to the local protection derived from the intact and impregnable mucous membrane, there are two factors producing immunity against diphtheria: the one is humoral in nature and its presence is determined by demonstrating and measuring specific antibodies in the serum; the other is the cellular factor, which is based on the varying faculty of the cells to generate antitoxins. Humoral immunity signifies absolute protection as long as antibodies are circulating. Cellular immunity, while unable to prevent infection, determines the intensity and duration of the attack. The later and the less efficiently the defensive mechanism of cells reacts to the morbid stimulus, the later the effects of the organisms and their toxins can be counteracted, and, naturally, the more opportunity is given for the diphtheria bacillus to develop its dangerous activity. In this way we are able to determine the malignant forms of diphtheria, which are due to the complete inability of the body to defend itself against the toxins of diphtheria.

8. Hyperchlorhydria in Children.—Dr. L. Berman calls attention to a symptom complex occurring in children usually between the termination of the first dentition and the beginning of the second, which is referable to a disturbance of gastric function, secretion, and mobility. Because of good therapeutic results obtained by the elimination of dietetic irritants and poor feeding methods and the giving of alkaline antacids these cases have been ascribed to hyperchlorhydria. So far as the writer knows there has been no study in the literature of a series of gastric examinations in supposed hyperchlorhydria of children, hence he reports cases in which gastric examinations were made, gastric juice being obtained one hour after a test meal consisting of a few biscuits and a glass of water. The analyses were made by a modification of the Töpfer procedure. They showed hyperacidity. The constitutional symptoms of these children were interesting. They were nearly all dark or sallow complexioned. They tended to be hyperactive, and yet tired easily, especially in the afternoon. They were all of the nervous type. This type of child seems to be predisposed to a development of hyperchlorhydria under irritant food provocation. This predisposition perhaps depends upon a certain relation to the adrenal-sympathetic-thyroid mechanism of the organism, which controls the nerves conducting inhibiting or stimulating impulses to the gastric cells. Although this remains to be determined, these cases point to the existence of a constituional type, perhaps dependent upon a constitutional hypoadrenalism, in which gastric irritation and bad hygiene produce hyperchlorhydria, hyperperistalsis, or disturbances of peristalsis of the stomach, and accompanying symptoms. All of these patients have done well under a general hygiene régime, with removal of the gastric irritants from the diet. Antacids and adrenal nucleoprotein seem also to assist in the restoration of conditions to the point at which symptoms disappear.

2. Framingham Community Health and Tuberculosis Demonstration: Certain Medical Results.—Donald B. Armstrong and P. Challis Bartlett present certain observations on this demonstration which has now been in progress for more than four years. Interesting aspects of the work have been studied under the following heads: (1) the amount of tuberculosis in Framingham; (2) diagnostic methods used in discovery; (3) study of arrested cases that have become active during the demonstration; (4) deaths from tuberculosis and a study of their histories; (5) present status of cases discovered during the demonstration. The amount of tuberculosis discovered in the early part of the demonstration, through all channels, indicated that one per cent. of the people had active pulmonary tuberculosis. The average number of cases of tuberculosis reported to the Board of Health in Framingham in the decade before the demonstration started was 13 per year. During the last four years the average number of cases reported to the board of health has been 43 per year. At the present time the number of cases of tuberculosis is considerably less than at any time since the demonstration started. A careful study has been made of the arrested cases of tuberculosis that have become active during this demonstration. Such cases numbered ten. Out of this number three had apparently no reason for reactivation; in two cases there were acute infections which seemed to be responsible for their upset, poor economic conditions seemed to be responsible for the reactivation in two cases, and three were due to lack of understanding or unwillingness on the part of the patients to care for themselves properly. During the four-year period out of a group of 376 individuals, including active, arrested, early and advanced types of the disease, 21 per cent. died. During the first year of the demonstration, through all sources of discovery, there were nine or ten active cases of tuberculosis to one annual tuberculosis death. At the present time the number has dropped, there being about five active cases to each annual tuberculosis death. The chief factors which seem to be responsible for the late discovery of tuberculosis cases which give the community every year advanced and dying patients that have not been known or treated for tuberculosis in the early stage of the disease are: the recluse type, which seems to be the main type never receiving any medical attention; failure of patients to seek medical advice early; failure of both physician and patient to use all the services at their command for early diagnosis of tuberculous disease; lack of complete annual medical examination, and lack of annual factory and school examinations.

3. Treatment of Acute Poliomyelitis with Immune Horse Serum.—Edward C. Rosenow gives a summary of the results of the treatment of acute poliomyelitis with immune horse serum prepared by repeated injection of the pleomorphic streptococcus from poliomyelitis in a series of cases during the epidemic at Davenport, Iowa, in 1917; during an epidemic in Dubuque, Iowa, in 1918, and in sporadic cases treated by himself and by physicians in various parts of the United States.

There were 58 cases in the Davenport epidemic, 58 in the Dubuque epidemic and 15 sporadic cases treated by the author. In addition to these 128 cases were treated by physicians to whom the serum was sent. The good effects noted at the bedside following the injection of the serum were in general proportional to the earliness of the injection. They were often striking, occurred after repeated injections, and were independent of the withdrawal of the spinal fluid. When improvement occurred it was with such regularity and in such marked degree in the early cases as to exclude accidental occurrence and to indicate that the absence of deaths, the low incidence of paralysis, and almost total absence of residual paralysis in patients treated before the onset of paralysis or with slight paralysis are due to the early administration of the serum. The results in the collective investigation corroborate in detail those which the writer obtained in both epidemics, and in the sporadic cases in which the primary data were obtained at first hand. Rosenow asserts that the conclusion that his immune horse serum has curative power in poliomyelitis, especially when given in the early stage, is warranted. Its general use in the treatment of this dread disease is indicated. The need for early diagnosis in suspicious cases by spinal puncture is again emphasized.

7. A Sign Occurring in Cases of Tabes Complicated by Charcot Joints.—Leo Eloesser observes that some tabetics have an analgesia of the bone but not of the skin. This may be tested by thrusting a pin through the skin and onto the bone. Such patients may have pain following an acute development of a Charcot joint. Their pain is felt in the distended skin and soft parts, not in the bone. This kind of pain does not subvert the theory that Charcot joints are due to trauma plus a lack of the warning sense of pain This dual sensibility of skin and periosteum would indicate that cutaneous and periosteal pain fibers run through the cord in different paths, and that one may be affected while the other is intact.

2. An Instrument Which Is Set in Motion by Vision or by Proximity of the Human Body.—Charles Russ has devised electrical and magnetic instruments for the purpose of demonstrating the force or ray which emerges from the human eye. The device consists of a delicate solenoid suspended in an aluminum box so that it is not influenced by air or heat currents. It is held steady by a magnet. Human vision can disturb the electrostatic state of this enclosed system. Having demonstrated this fact, he constructed some light condensers and found that they also were affected not only by the human gaze, but by the body generally. With the application of heat these motions were much reduced, but not abolished. It is known that there is an electrical change in the retina accompanying vision, and also electrical changes in the muscles of the eye when in action, and these will have associated electrical fields. Whether the fields from these sources are adequate to account for the effects cannot be answered at present.

3. The Etiology of Bacillary Dysentery in Asylums.—W. S. Dawson and W. Moodie state that in spite of all efforts to control it dysentery in the past has been the cause of a large amount of the sickness in asylums, as well as a considerable percentage of the mortality. Thus, during the year 1919, in 80 county and borough asylums 1722 cases of dysentery were notified and of these 20 per cent died. The present state of our knowledge regarding asylum dysentery is summed up in the words of Tidy, who says in his "Synopsis of Medicine," "No specific organism is present, but bacteriological and serological investigations have indicated bacilli of the Flexner group." A small series of cases in the Claybury Mental Hospital were studied during the early part of this year which yielded such definite results that they are worthy of note. Contrary to the accepted view that dysentery is a disease of hot weather and is generally spread by flies, the high incidence of cases in Claybury occurs during the winter months. Seven cases occurred during the first four days of the outbreak, and from the feces of all of these a bacillus of the Flexner type was cultivated. The patients affected were isolated in single rooms and a strict watch was kept for any suspicious cases of diarrhea, several of which occurred during the subsequent two months, and were investigated. During that time an identical bacillus was found in five more cases. The system of isolation of positive cases was persisted in, and, at the time of writing, no case of clinical or bacteriological dysentery had occurred for over a month. The writers conclude that it is of paramount importance that the feces of all cases of clinical dysentery and diarrhea be examined in the laboratory. Having in mind that primary attacks and relapses may be so slight as to pass unnoticed, and the possibility of every case remaining a chronic carrier, very strict observation and a system of isolation are necessary in order to prevent the spread of the disease. Agglutinins are present in the blood of affected patients only after the fourth week of the disease, and therefore agglutination tests are of very little diagnostic value.

Serological Types of Pneumococci in Lobar Pneumonia.—Fred Griffiths contributes his observations on the serological characters of strains from 100 cases of lobar pneumonia which he has classified according to the American method. Experiments in immunization carried out on guinea pigs suggest the necessity of using considerable amounts of culture and the probability that more active and more permanent agglutinating serums can be prepared by the use of living culture than with culture killed by heat. In this series of 100 consecutive cases of lobar pneumonia, 24 were shown to belong to type 1, 35 to type 2, 10 to type 3, and 31 to type 4. In the American series types 1 and 2 taken together account for about 62.6 per cent. of the cases; in this series the corresponding percentage is 59. The incidence of cases of lobar pneumonia attributable to type 4 pneumococci appears to be higher in England than in America. Regarding the specificity of types Griffiths finds that the serological groups of pneumococci which have been designated types 1 and 2 by the American observers are equally well defined. Type 3 differs from the first two not only serologically, but generally also in distinctive morphological and cultural characteristics. The simple agglutination test is sufficient for identification of each of these three types, and it is unnecessary to apply the method of absorption of agglutinins. The unclassified strains in this series, designated type 4, did not react with any of the three type serums, 1, 2, and 3, in dilutions of 1:20. This group of strains contains many types. Six types, including the American atypical types 2 A and 2 B, have so far been defined in the present investigation, but the classification has not been completed. It is possible that if serums from unselected strains are used cross-agglutination between the three chief types and their respective serums may occur. Agglutinating serums prepared from horses appear to be less selective than rabbit serums.

1. Evolutionary Wounds. Arthur Keith.
2. Stillbirth: Its Causes, Pathology and Prevention. Francis J. Browne.
3. The Psychologist in Public Life. H. B. Brackenbury

2. Stillbirth: Its Causes, Pathology, and Prevention.—Francis J. Browne bases this contribution upon the post-mortem examination of 200 consecutive cases of stillbirth and neonatal death occurring in the Edinburgh Royal Maternity Hospital from August 1, 1919, to November 30, 1920. Of these 120 were stillbirths and 80 neonatal deaths. Of the 120 stillbirths asphyxia was the cause of death in 49, or 40 per cent., of which 11 occurred before labor and 38 during labor. The

figures show that asphyxia is eight times as likely to occur in breech as in vertex delivery. Most of the cases of asphyxia might have been prevented by adequate antenatal supervision which would have led to the discovery of such conditions as contracted pelvis, excessive size of the child, breech presentations, and albuminuria, and to the institution of preventive treatment. In the series are included 22 macerated fetuses, in 14 of which the cause of fetal death was syphilis, in 3 albuminuria, in 1 diabetes, and in 4 the cause was doubtful. Of the 200 cases there were 59 cases of cerebral hemorrhage, or 29.5 per cent. and of these 20 were delivered by breech and 39 by vertex. There were 22 nonforceps cases with cerebral hemorrhage, and all occurred in premature infants. The liability to cerebral hemorrhage seemed greatest between seven and seven and a half months, while at eight and a half months the liability seemed to be no greater than at term. In 35 of the 59 cases of cerebral hemorrhage there were tears complete or incomplete of the tentorium cerebelli. It appears that breech delivery is sixteen times as likely to give rise to tentorial tears as vertex. Further, in every case of breech delivery at term there seemed to be some degree of tentorial tearing. The points to be kept in mind in the prevention of cerebral hemorrhage would seem to be: (a) Avoidance of breech deliveries, by cephalic version of breech presentations at a period when this is always possible, not later than the seventh or eighth month. (b) Avoidance of difficult forceps deliveries; this is only possible by antenatal supervision of every case. (c) Avoidance of the induction of premature labor, certainly before eight months, better still before eight and a half months. (d) Manual dilatation of the partarient canal for the passage of the premature infant and preservation of the membranes unruptured as long as possible. The latter has also an important bearing on the infection of the newborn. There were altogether 35 cases of syphilis, including 14 macerated fetuses. From a study of these cases it is evident that the post mortem diagnosis of syphilis is not always a simple matter, but that it frequently entails a careful weighing of all the available evidence, the obstetrical and clinical history of the mother, the Wassermann test, the placenta, a complete naked-eye and microscopical examination of the fetal organs. Pneumonia is a frequent cause of death in infants during the first week after birth, and accounted for 21 deaths out of 89, or 26 per cent., in this series. There is a type of pneumonia that seems to be peculiar to the new born infant, an acute hemorrhagic pneumonia, in which the etiological factor in most instances is organismal, though there is some evidence to support the theory that in some instances it may be in the nature of an anaphylaxis. There were 18 cases of hemorrhage into the suprarenal body, and all were born dead except two. The great fact that emerges from this entire investigation is that a very large percentage of the stillbirths could have been avoided by adequate antenatal supervision.

3. **The Psychologist in Public Life.**—H. B. Brackenbury is of the opinion that experience in the great war has created a greater revolution in psychology than in any other science. He says the stage of evolution at which mankind has now arrived is one in which the individual is seeking a closer and more stable adjustment to the human society of which he is a part, and in which such societies are seeking a closer and more stable adjustment to one another. The adjustments required are mainly adjustments of mind. Biological progress has become predominantly psychological in character. We need to recognize that the psychologist has become a person of paramount importance in our social and public life. Properly to train the child so that his adjustment shall be easy and as far as possible automatic; appropriately to restrain the adolescent so that his antisocial actions shall be controlled and his liability to antisocial behavior lessened; wisely to direct adult activities so that specific abilities may be of the greatest use to the community, are functions which without the psychologist cannot be performed. Without his aid no statesman can safely attempt to reconcile the interests of different classes and to reorganize international relationships. A closer knowledge of the collective mind of the medical profession (not its opinions on a particular subject so much as its general characteristics) would smooth the path of many a minister of health. Psychology as an abstract science and as an applied art is becoming more and more a matter of intimate concern to every one of us. America has been wiser than the rest of the world in that the first things she did on entering the war was to mobilize her psychologists. In preparation for the industrial competition of the near future she is pursuing the same methods. We have learned to apply the truths of natural science; it is time that psychological truths should be applied with the same courage and conviction.

4. The Diagnosis and Treatment of Tuberculous Coxitis. A. W. Calloway.
5. Malnutrition in Children After the First Year of Life. L. T. Royster.

3. **Diabetes Mallitus in the Negro Race.**—I. I. Lemann recalls that ten years ago he was able to show from the statistics of the Charity Hospital, New Orleans, that the relative incidence of diabetes was greater in the white than in the negro race, the rate being 0.72 per thousand in the former against 0.47 in the latter. Such a difference, however, hardly warrants the conclusion formerly held by some that diabetes is rare in the negro race. A recent analysis of the Charity Hospital reports during the period 1909-1919 has confirmed the impression made ten years ago in a remarkably accurate way and has added, at least, the very valuable evidence that the increase in diabetes has fallen upon both races with practically equal force. Comparing the two periods the total incidence of diabetes has increased from 0.63 per thousand in the period 1898-1909 to 1.2 per thousand during the period 1910-1919, or an increase of 90 per cent. The incidence among the whites rose from 0.72 per thousand to 1.4 per thousand, or 94 per cent.; that among the negroes rose from 0.47 per thousand to 0.86 per thousand. It therefore seems safe to say that whatever influences have contributed to the increase of diabetes have affected the white and negro races alike. Analyzed from the standpoint of Warthin's contention that syphilis plays an important rôle in the production of diabetes, one would expect, in view of the syphilization of the negro, to find diabetes more common in the negro than in the white race, but diabetes is less common among the negroes than among the whites. It therefore seems fair to conclude that syphilis is playing no important part in producing diabetes. This, however, is far from saying that syphilitic pancreatitis does not at times produce diabetes. Attention has frequently been drawn to the effect of nervous influences in the production of diabetes. The negro race is to a great degree free from these influences. The mental and nervous make-up of the negro is in marked contrast to that of the Jews, among whom diabetes is disproportionately frequent.

Schweizerische medizinische Wochenshrift.

June 16, 1921, 7, 24

Further Contributions on the Nature of Herpes Febrilis.—Doerr and Schnabel recapitulate our knowledge of the propagation of simple herpes from cornea to cornea in the rabbit. Many pathologists have taken up the subject. It has been found that a general infection may result, which in the neurotropism of the exciting cause presents a strong resemblance to epidemic encephalitis. The earliest attempts to convey the disease from brain to cornea were unsuccessful, although it may be propagated from brain to brain. Later numerous reports were received of positive inoculations of the cornea with infected brain matter, and the evidences of an autonomous laboratory disease were complete. The authors have continued their work with human herpes material, inoculated upon both mankind and rabbits and later guinea-pigs, the eyes of which are readily infected. Different strains showed marked difference in virulence. The eye of the rabbit becomes immune to further inoculation. The contrary is often

seen in the human clinic, for one attack of spontaneous herpes often seems to sensitize the part affected, especially in herpes progenitalis, which may recur again and again for many years. In the experimental rabbit the immunity is not permanent, so that this difference is not absolute. Curiously, immunity toward further inoculation in the rabbit's cornea extends to inoculation with epidemic encephalitis, and, further, it was also impossible to convey the latter to these immunes directly into the brain by subdural injection. The authors regard the trail of the proof of identity of the two diseases as a very warm one and hope to announce success at an early day.

Schweizerische medizinische Wochenschrift.

June 30, 1921, li, 26.

Traumatic Herpes of the Cornea.—Stocker, who asks if traumatic herpes cornea is a possibility, answers in the affirmative, as a result of both experimental and clinical research. The febrile type of this lesion is, of course, well known; and in order to discriminate between the two types of lesion, fever would presumably be absent in the traumatic form, but this point requires study. Traumatic herpes of the cornea is known in literature and the author cites a number of cases, but the autonomy of the lesion has not been formally shown. Gamper in 1917 reported a case of "traumatic febrile herpes" of the cornea, but he was criticized by Stockmeier, who stated that the case had not been proven. The author has seen 94 cases of herpes of the cornea in 10 years, of which 11 (11.7 per cent.) had followed trauma and had been unattended by fever. From several other clinics the percentages obtained were from 4 to 18, so that 11 is a fair average. Not only should fever be absent, but there should be no other evidence of a constitutional reaction. The author gives in detail his 11 cases and analyzes them. The incubation period was short—2 to 4 days. In the majority of cases the violence was blunt, but in 3 there was penetration by a foreign body. Herpes traumaticus must be distinguished from the inoculated herpes of the laboratory which may be followed by general infection and which is presumably due to the action of an unknown specific exciter.

Gazette des Hôpitaux.

May 31, 1921, xciv, 43.

Adrenalin in Asiatic Cholera.—Naamé of Tunis contributes a short article on this subject. He has made use of this treatment since 1911, and the idea of it came to him through the resemblance between the cholera syndrome and hypoadrenia. Sergent, Sajous, and other authorities have mentioned the same resemblance, and the treatment has been widely employed by others besides the author. It may be shown in the laboratory that the cholera toxin causes congestion and swelling and at times hemorrhage of the adrenals. In human cholera there are the same autopsy finds. Carriers of cholera vibrios who remain immune doubtless have protection from sound adrenals. The failure of preventive cholera vaccine to show any curative effect may be due to the fact that the adrenals have become compromised. In regard to the rationale of the adrenaline defense Marie assumes that the hormone neutralizes the soluble cholera toxin. The cholera patient shows a remarkable tolerance to adrenaline. In his recently published monograph on cholera, Violle gives Naamé full credit for the introduction of this very successful plan of treatment which is now in use in the Indies and in Italy. It is, in fact, the classic method when combined with massive intravenous injections of saline solution.

Importance of Buccodental Infection in Pathology.—Watton and Aimes contribute a paper on a subject only too common in the United States, but relatively infrequent in European literature. It is by no means a new subject in France, for even as far back as 1859 authors wrote on the socalled "buccal cachexia" by which sepsis of gingival origin was meant. When, in 1872, Piorry coined the word "septicemia" he even had in mind infection which originated from pyorrhea. In 1900 Sebileau changed the conception of sepsis to one of buccal toxemia. Since that period Americans and English have built up their doctrine of buccal focal infection with special reference to the teeth. But even in the dental type the French had a pioneer in Ferré, whose article appeared in 1896. As the idea of a buccal sepsis spread it took into account many conditions not ordinarily enumerated in focal infections. Thus the term may be applied when buccal pneumococci become virulent and set up pneumonia and bronchitis or when swallowed saliva or buccal pus sets up gastroenteric infection. Galippe as far back as 1890 attributed certain cases of diabetes to buccal infection, and of much greater interest, because eventually confirmed, was his statement that nephritis could originate in the same manner. French stomatologists evidently believe that the doctrine of apical focal infection has been pushed to extremes in America, while an American, Goldmann, has made some uncomplimentary remarks about the backwardness of French stomatologists in recognizing the importance of this sequence. The author in question seems to contradict himself in part, in that he accuses the Frenchmen of insufficient care of the national teeth, while at the same time critiicizing them, it would seem, for not recognizing a state of affairs which exists chiefly in the land of the most advanced dental technics.

Inactivation of Complement by Ultraviolet Rays.—Kagawa concludes his long article as follows: The complement in 10 per cent. physiological solution becomes partly inactive under the action of ultraviolet rays. This inactive fraction becomes active again by the addition of the intermediate link, but not by the terminal link. This is owing to the fact that inactivation has been due to destruction of the intermediate link, which is less light-resistent than the terminal link. If one compare the two links when dissociated one finds that the terminal link is the more stable. The nature of the phenomenon rests on the fact that the moderate amount of heat produced by the actinic rays favors the combination of the intermediate link and the red corpuscles. The resistance of the two components varies with the *milieu*—whether combined or separate. Moreover, in saline solution the intermediate link rapidly becomes inactive without any action on the part of the actinic rays. In tests involving the intermediate link the latter should not be placed for long in suspension in artificial serum. The complement partly inactivated by heat always contains a quantity of intermediate link sufficient to give complete hemolysis when assisted by the presence of the terminal link.

Etiology of Sodoku.—Stretti publishes a preliminary communication on this subject, with the assistance of Mantovani of the Hygienic Institute. An elderly woman was bitten by a rat in October, 1920. She went through a rather severe experience with sodoku, which was treated successfully with intravenous neosalvarsan. In the meantime, guinea pigs inoculated with the patient's whole blood gave a positive result. In the deceased animals, autopsy showed lesions which were comparable with those of human sodoku. Heart's blood from these animals subjected to the ultramicroscope revealed the existence of organisms which appeared to be spirochetes in two varieties. Passage through several animals was successful, and with repeated passage a hemorrhagic component was noted. The organisms were also found in the internal organs and especially in the liver. The two forms, long and short, of spirochetes remained in symbiosis with continuous passage, the short taking the lead in frequency. The only other positive finds concerning the spirochetic etiology of this disease are those of two Japanese authors in connection with the sodoku of that country.

Book Reviews.

THE THIRTEENTH GREATEST OF CENTURIES. By James J. Walsh, K.C.St.G., M.D., Ph.D., LL.D., Litt.D. (Georgetown), Sc.D. (Notre Dame), Medical Director School of Sociology, Fordham University; Professor of Physiological Psychology at Cathedral College, New York; Lecturer in Psychology, Marywood College, Scranton, and St. Mary's College, Plainfield; Trustee of the Catholic Summer School of America; Member of the New York Academy of Medicine, of the German and French and Italian Societies of the History of Medicine, etc. New York: Catholic Summer School Press, 1920.

THIS book, on its first appearance in 1907, caused something of a shock to many who were still governed by the teachings of their school days regarding the "dark ages," the very middle of which was the thirteenth which Dr. Walsh boldly proclaimed the greatest of centuries. And if he did not prove his case to the entire satisfaction of all his readers which, being a man of sense, he probably did not expect to do, he certainly did show them that the thirteenth century was great in art, education, literature, architecture, law, and medicine, and that many of the conceptions popularly held regarding that period are misconceptions. The alleged Bull of Boniface VIII against dissection, for example, which is referred to in most works on the history of medicine, is shown by Dr. Walsh to have been directed against the practice of boiling the bodies of those who died away from home so as to make it possible to bring them back to be buried among their kinsfolk. The uninitiated layman may not see anything contrary to faith or morals in this practice, and so may regard its prohibition as uncalled for, but it certainly had nothing to do with dissection.

The present edition is enriched with a large number of illustrations of buildings, statues, paintings, and other works of art dating back to the thirteenth century. Those who have never read this interestingly told history will do well to do so; it is an education in itself.

ABHANDLUNGEN AUS DER NEUROLOGIE, PSYCHIATRIE, PSYCHOLOGIE UND IHREN GRENZGEBIETEN. Heft 10. DIE ABDERHALDENSCHE REAKTION mit besonderer Berücksichtigung ihrer Ergebnisse in der Psychiatrie. Von Privatdozent Dr. GOTTFRIED EWALD. Berlin: S. Karger, 1920.

IT was a great disappointment when, after a brief period of enthusiastic acclaim, the Abderhalden reaction failed to meet the expectations of medical men and gradually fell into disuse. The theoretical basis for the test was so logical and attractive that great things were expected of it but the results were so irregular that it proved of little value. Ewald has reviewed the subject quite thoroughly and has tried it out on a large series of mental cases. He finds it most constantly positive in dementia precox and positive in about one-half the cases of hysterics, psychopaths, and manic-depressives. In other forms of mental diseases the reaction is either generally negative or else so irregular as to be devoid of any diagnostic significance. On the whole, it may be said that the practical value of the Abderhalden reaction is slight, certainly not sufficient to repay the time and labor which it demands. This brochure has served a good purpose in emphasizing the limtiations of the reaction.

PRÉCIS DE THÉRAPEUTIQUE MÉDICALE OTO-RHINO-LARYNGOLOGIQUE Par G. DE PARREL, Ancien Chef de Clinique à l'Institution Nationale des Sourds-Mirets de Paris, etc. Preface du Dr. PIERRE SEBILEAU. Paris: A. Malvine et fils, 1921.

THIS volume contains 671 closely printed pages, in which all nonsurgical therapeutic resources are considered in association with dressings and local applications. A general section answering to materia medica and pharmocology is followed by chapters on the general and special treatment of diseases of the ear and mastoid process, the internal ear and deaf-mutism, the nasal cavities and sinuses, the naso-pharynx, oro-pharynx, pharynx, larynx, and trachea. These sections occupy the first half of the book. Next in order come vaccinotherapy of the combined regions; physiological therapy (orthophony and anacusis; labrology or lip reading); physical therapeutics (electrotherapy, radiotherapy, climatotherapy, and hydrology.) The outstanding feature of the work is the technique of treating stammering and other speech anomalies, auditory reeducation, lip-reading, etc., this instruction constituting a book within a book.

PRACTICAL CHEMICAL ANALYSIS OF THE BLOOD. A Book Designed as a Brief Survey of this Subject for Physicians and Laboratory Workers. By VICTOR CARYL MYERS, M.A., Ph.D., Professor of Pathological Chemistry in the New York Post-Graduate Medical School and Hospital. Illustrated. Price, $3.00. St. Louis: C. V. Mosby Company, 1921.

READERS of the *Journal of Laboratory and Clinical Medicine* who have derived pleasure and instruction from the contributions of Dr. Myers on the chemistry of the blood will be glad to know that they have now been republished, together with additional matter in permanent book form. There are chapters on non-protein and urea nitrogen, uric acid, creatinine, blood sugar, carbon dioxide combining power, cholesterol, and chlorides, and an appendix containing descriptions of various tests, methods of estimating the amount of total solids and total nitrogen in the blood, and simple methods of quantitative urinary analysis. The work is authoritative and will be found a valuable guide for laboratory workers as well as for the many practising physicians who have followed Osler's advice of many years ago to equip themselves for making all necessary blood and urinary tests in their own offices.

LEHRBUCH DER NERVENKRANKHEITEN für Studierende und praktische Aerzte, in 30 Vorlungen. Von ROBERT BING, Professor an der Universität Basel zweite, vermehrte und vollständig neubearbeitete Auflage. Preis 100 marks. Berlin und Wien: Urban & Schwarzenberg, 1921.

THE original edition of this work appeared in 1913 and is available to the reviewer only in the American edition published in 1915. The number of pages in the second German edition is 665, which is nearly 200 more than in the American edition, but the pages of the latter are notably larger. The number and titles of the chapters show no new departures over the original edition. The author has given special revision and elaboration to the sections on the peripheral nerves, neurosyphilis, acute infectious diseases, dysglandular syndromes, psychoneuroses, and cerebral and cerebellar legions. He has been conservative in his attitude toward military neurology, for Switzerland as a neutral country had no first hand experience with the subject.

OEDEMA AND NEPHRITIS. An Experimental and Clinical Study of the Physiology and Pathology of Water Absorption in the Living organism. By MARTIN H. FISCHER, M.D., Eichberg Professor of Physiology in the University of Cincinnati. Third and Enlarged Edition. New York: John Wiley and Sons, Inc., 1921.

THIS third and enlarged edition of Dr. Martin Fischer's well known work contains several important additions, though the main body of the book is practically unaltered. The author's concept of the hydrophyllic colloid is the basis of the work previously done and it is further developed here in relation to acid-intoxication. This latter term needs further explanation, for it is a fundamental question and in the light of biological chemistry hydrogen-ion concentration and titration acidity should be defined and distinguished from the author's use of the term "acid-intoxication." The whole concept of edema in relation to "acid-intoxication" as affecting all the tissues of the body is a fundamental question of pathology as regards the circulation of blood and lymph in every part of the organism, not merely in the matter of parenchymatous nephritis and the processes of repair in the kidney. The clinical test of the author's views is the real one and the successful treatment of edema by the author's methods is the warrant for more extended use of these methods, while the explanation and more accurate definition of his terms may be left to more extended research and observation in the course of time. Other substances in addition to acids (including some alkalis) may and do increase the hydration capacity of colloids. But the practical application with success of the author's methods demands and deserves still more extended use.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 28, 1921.

THE PRESIDENT, DR. GEORGE GRAY WARD, JR., IN THE CHAIR.

Cancer Growth in the Light of Embryonic Growth.—DR. CHARLES R. STOCKARD spoke of tumor growth and tumor-like growth from the standpoint of normal growth. He said that normal growth was a problem about which very little of an exact nature was known and it naturally followed that very little was known about the biology of tumor growth. It might be said that tumor growth was a modification of the normal growth processes, and this was true in spite of what its causes might be. In discussing his subject he considered briefly two entirely different types of tumor growth, namely, the ordinary teratoma, or embryonic inclusions, and, secondly, the various tumors of the adult and old age. Teratoma from the standpoint of embryology was an accessory growth which started as a modified budding process. All young embryos had many potential growing points which constantly became fewer as the adult condition was attained. In plants where there was a simple generalized growth the processes were more easily observed. After growing for a time a plant stopped with its apical bud coming to a rest. It rested for a while until there was an accumulation of growth stuffs when it again began to grow. This might happen many times in the course of the development of the rapidly growing plant. The new growth usually occurred as a single shoot from the apical bud, but now and then this did not take place and instead of a single terminal shoot there was a double formation due to a growth from the apical and also one from the upper axillary buds. When the central bud grew the others were suppressed. Reactions of this kind illustrated the results of disturbance in balance of growth. When the terminal bud was cut away and the two upper axillary buds sent off shoots it frequently happened that one of the axillary buds was larger and better than the other. The better shoot grew at the expense of the smaller and tended to suppress it. This was a common condition of balance between growing parts and the potential growing parts. The same principle was true among animals. By slowing down the growth rate two buds might be produced instead of one. This Dr. Stockard demonstrated by illustrations showing embryo fish in which growth had been inhibited and as a result there were two budding heads instead of one. Certain of the illustrations showed both of the components alike; there was no deformity; they were simply double individuals. But each of these components of the double organism exerted its effect upon the other component and this was important in connection with growth balance. These points were also important in their bearing on the origin of teratoma. When two parts were equal in size they were normal in structure, but when there was a difference in size the smaller one was always deformed. Some of the heads became amorphous and finally there might be only a nodular formation. This might not grow but might become simply an inclusion and would be found as an embryonic mass inside of the larger component. If this inclusion later began to grow a teratoma resulted, and under certain conditions such as those mentioned the teratoma would come in the head or neck. Other conditions of Siamese twin formation with one small component part resulted in abdominal and pelvic inclusions. Teratoma had been thought to be due to a growing germ cell, as from the germinal cells of the testicle. But it had been shown that there was no growth from the male germ cell. If it were true that teratoma had their origin only from the reproductive gland of the host they would all be found in the abdomen, but this was not true; they were found in all parts of the body. It had been shown that these inclusions in the double type of organism always took place in that part of the body in which they originally occurred. Passing on to a consideration of tumor growths and the general cessation of all normal growth in older individuals from the standpoint of actual normal growth reactions, Dr. Stockard based his remarks upon experiments on the interaction among the organs of the developing individual. In the interpretation of the cause of tumors the fact that the condition was more frequent in the adult and old individual than in the young was to be recognized as of deep significance. The fact that there was in interaction and a growth inhibiting effect exerted among proliferating tissues in the individual was a second point of great importance. In the young rapidly growing and developing person almost all organs and tissues were increasing in amount through multiplication of their cellular constituents. Organs however were definite and limited in their growth and growth in general tended to cease as the body approached its adult proportions. Finally in the old individual cell proliferation became almost entirely confined to the germinative layer of the skin, the lining epithelium of the alimentary tract, the testes in the male, and the production of red blood corpuscles. Even these processes became feeble with increase in age, and new cells were not abundantly supplied. This was the normal course of events. The size and proportion of parts were largely determined by heredity but might be seriously interfered with by irregularities in environment. A slowing of the developmental rate at particular times might largely suppress the growth of certain organs rendering them abnormally small in size and insufficient in their function. Again it might rarely happen that one organ took on an excessive growth and attained a size entirely out of normal proportion. There was thus a frequent lack of proper balance and adjustment among the several organs of the developing body. All parts of the body might be thought of as having more or less to do with the ultimate growth of the whole. On becoming adult a state of apparent balance was maintained. Growth was largely confined to the repair of natural loss and the maintenance of this state of adult balance. Under such conditions there still remained considerable regenerative powers following injuries of various kinds. The regenerative growth following injuries to the adult animal might become morbid in degree and without regulation thus give rise to tumor-like conditions. Such a growth might rarely occur even in the immature body, but in this case one would expect to find the growth proportions among the tissues in general to be abnormal and distorted. Thus, juvenile tumor conditions were probably associated with other anomalous structures. Tumors in the adult would be expected to occur more frequently in certain families, since growth balance and proportions were hereditary characters, and on the state of these the tumor growth largely depended. In the old individual with but little normal growth still in existence, there could be on the basis of this interpretation, but slight inhibition to any regenerative process that might be set up. Such animals on account of their old condition usually regenerated slowly but following continued trauma, active regenerative growths were frequently begun and not being under inhibiting control of any other active growth processes, this regeneration attained an excessive, distorted and malignant condition. All very old animals no doubt experienced a considerable amount of trauma and if they lived long enough almost all of them might possess some tumor growths. A rat at three years of age was as old as a man at sixty, while a guinea pig did not become old until it reached the age of five years. Rats and mice were often kept for laboratory use until they were two years old while guinea pigs were seldom kept until they reached a correspondingly advanced age. Consequently tumors were said to be uncommon among these animals. However, among the old individuals of their stock a considerable percentage of tumor bearing ones had occurred. So, it might be inferred that if as many really old guinea pigs were observed as of old mice and rats cancer might be found to be almost as common among guinea pigs as among rats and mice. Finally, it might be supposed that every mammal would develop some form of cancerous growth should it chance to live until extreme old age, since one of the conditions of old age was a loss of the general growth-

regulating processes so necessary in young and growing individuals.

Some Factors to be Considered in the Surgical Therapy of Cancer of the Rectum.—Dr. JEROME M. LYNCH stated that this was a very old subject, but that when we considered the fact that tumors in the rectum remained stationary longer than in any other part of the body; that the rectum was the most accessible of all the viscera; that most tumors of the rectum lay within seven to ten centimeters of the anus and with the proctoscope could be diagnosed at any period; that when discovered early they could be removed; when the fact was taken into consideration that of 600 cases of tumor of the rectum coming under the speaker's observation, the average period of their existence before the diagnosis was made was eight months; there seemed to be something wrong. Nearly all cases of cancer of the rectum were pretty well defined. Usually the onset was marked by constipation and a desire to move the bowels with an explosive effort. At first this desire was manifested on rising in the morning; later it became more frequent, occurring not only in the morning but several times during the night. Disturbances of the stomach or other parts of the alimentary canal were frequently associated with cancer of the rectum and that was why many people having cancer of the rectum were treated for stomach symptoms and came late to the surgeon. It seemed to him that it was a simple matter to make the diagnosis. There was nothing that resembled cancer of the rectum except an old inflammatory condition, and occasionally one found a malignant tumor engrafted on such an inflammatory condition. In addition to examination of the rectum with the finger and the proctoscope, biopsy had the sanction of many surgeons. Dr. Lynch thought this a very bad practice. It was hardly ever necessary to excise a specimen in order to make a diagnosis. The only conditions that might be mistaken for carcinoma of the rectum were diverticula, hyperplastic tuberculous lesions, and syphilitic stricture. Syphilis of the rectum was very rare; he did not believe he had seen five cases in twenty years. Hyperplastic tuberculous lesions were more often found in the sigmoid than in the rectum. Tuberculosis of the lower bowel was rare, though if the patient had tuberculosis of the lungs it might be suspected. When the diagnosis was once made Dr. Lynch said he thought the radiologists would agree that they were in a better position to treat the patient after the tumor had been removed than before. It was difficult to tell when a tumor was inoperable until one saw it at an exploratory operation. In suspected carcinoma of the rectum it was important that an exploratory laparotomy be performed, as the finding of metastases in other parts of the abdomen might show that operation on the rectum would be futile. If the sigmoid was long enough so that it could be brought down an artificial anus in the natural location was better than a stoma on the abdominal wall. There were many patients with stoma for conditions other than carcinoma, who were very comfortable and suffered little inconvenience. Colostomy was always done when the growth was within 2 cm. of the anus in order to prepare for extensive removal *en bloc* if this was necessitated by extensive lymphatic involvement. As soon as a diagnosis of cancer was made colostomy should be insisted upon. Colostomy should not be postponed until obstruction took place. The advantages of early colostomy were that it reduced inflammation, often converted an inoperable into an operable case, obviated intestinal obstruction, and its accompanying symptoms of pain, constant secretion and defecation; stopped hemorrhage, and permitted rest and sleep. As to operations, Dr. Lynch said he had no one operation to suggest. One must choose the method best suited to the conditions present in the individual patient at the time of operation. Any particular operation which one might undertake might require modification, so one must not start out with any set idea of what he was going to do, but must simply meet conditions as they arose. The Kraske operation was *passé*. This operation was devised to save the lower bowel. Every time one did that operation he left a stricture, which was due rather to the interference with the terminal blood supply than to absence of peritoneum. It was a surgical axiom that the amount of scar tissue was in reverse ratio to the blood supply. The perineal operation was the operation of choice in very fat or in extremely debilitated people, because these people did not stand abdominal operations of any kind well. In all cases he preferred to remove the coccyx, because it gave better drainage and obviated the necessity of closing the dead space between the anus and the coccyx. Cancer of the rectum remained stationary for a long time. In the speaker's series of cases an average of eight months elapsed from the time symptoms manifested themselves until the diagnosis was made and 26 per cent. of these patients were well after five years; this was doing well. Cancer metastasized rapidly by way of the lymphatics, as was well known, and in the rectum the supply of lymphatics was small; hence the rectum was a place where something could be done by surgery, the *x*-ray, and radium. The public must be educated to the fact that examination of the rectum was as necessary as examination of the tonsils or other parts of the body, and that a general physical examination was always necessary no matter what the patient was suffering from. Then people should be educated to the advantages of an early colostomy in the presence of cancer.

The Relation of Radium and Roentgen Ray Therapy in Cancer.—Dr. ISAAC LEVIN presented this contribution which was illustrated by lantern slides. He stated that the mechanism of the action of radium and the roentgen rays was the same in all parts of the body, and a comprehensive description of it could not be given without illustrating it by the results obtained in malignant tumors in different parts of the body. The morphological changes which occurred in carcinoma or sarcoma tissue under the influence of the rays were observed in the tissues themselves, and were manifested by the vacuolation of the protoplasm, pyknosis of nuclei, karyolysis, and ultimately complete necrosis of the cell. The cellular changes were accompanied by a round celled infiltration, which was subsequently changed into dense sclerotic connective tissue, poor in blood vessels. This new connective tissue formation ultimately dominated the picture to such an extent that some observers maintained it was the only direct effect of radiation, while the destruction of the tumor cell was secondary and due to lack of nutrition. The clinical, pathological, and biological studies of the writer, in association with B. Joseph and M. Levine, indicated that the first effect of the rays was directed directly on the tumor cells. This effect consisted in the inhibition of the proliferating power in the sterilization, as it were, of the cancer cells. The degeneration and destruction of the cancer cells and the formation of sclerotic connective tissue took place subsequently through the action of the rays; moreover this cell degeneration and cell death might not be due directly to the action of the rays, but might take place in the natural course of the life cycle of the cancer cell. This cycle consisted of a youth, a period of development maturity or a period of function, and senility or a period of degeneration, which gradually led to death. In parenchymatous organs the first period was usually completed during embryonic life or at a very early age; the second period continued through the whole life of the organism, and the third period was attained at the old age of the organism or near its death. The life of an individual cancer cell, on the other hand, was very short, and the whole process took place continually, irrespective of any intrinsic aid. But in a malignant tumor the majority of the cancer cells were quickly rejuvenated before they reached senility through the fact that each cancer cell was divided into two daughter cells. *When the rays arrested the proliferation, then the cancer cells, without any further outside aid, matured and degenerated.* Such a cell might not degenerate and though potentially a cancer cell, might be resistant to the rays. The round cell infiltration, which surrounded the group of radiated cancer cells and which was subsequently changed into dense sclerotic connective tissue, was of secondary occurrence, though for practical purposes it was of greater importance than the destruction of the cancer cells themselves. The importance of the connective tissue consisted in the facts that, after the most

perfect results of radiation, there might remain a certain number of viable though stunted cancer cells; the dense connective tissue wall surrounded these cells and kept them in check. The formation of this connective tissue around the cancer cells was not due to the direct influence of the radiations; raying of other conditions like thyroid gland, cheloid, etc., was not followed either by cell infiltration or by connective tissue formation. The experimental investigations of the writer indicated that this connective tissue formation might represent an attempt on the part of the organ to protect itself against the further growth of the cancer by walling it off from the normal tissues by a connective tissue barrier. The mechanism of the action of the rays on malignant tumors could be demonstrated most clearly in the study of the influence which radium exerted on carcinoma and sarcoma of the skeleton. The metastasis usually began its development within the marrow, and when the nodule of carcinoma was small, the surrounding bone marrow appeared quite normal. As the tumor nodule increased in size, it approached and invaded the compact osseous tissue or the compact osseous partitions of the cancellated bone. Then there began to appear characteristic changes in the bone tissue. These changes were of two types, namely, osteoplastic, in which extensive new bone formation took place around the metastatic tumor; and osteoporotic, in which the changes consisted in destruction of the compact bone. The studies of the writer had shown that both conditions might be present alongside one another. Most frequently the metastatic nodule increased in size, suppressed the power of the organism to create new bone, and progressively destroyed the old bone. The spontaneous healing power of the organism was thus quite imperfect and came into play very rarely indeed. In a previous communication the writer had shown that radium therapy might enhance the healing power of the organism, destroy at least a major part of the malignant tumor, and surround it with newly formed bone. A case illustrating such a result was that of a woman, 54 years of age, who consulted Dr. Willy Meyer for carcinoma of the left breast. In the course of the examination there developed a pathological fracture in the middle of the shaft of the right humerus. A roentgenogram showed complete destruction of the bone of the shaft of the humerus in an area over an inch long. Two weeks after the first radium application the roentgenogram showed a callus formation and the two ends of the bone in good position. The patient could support her arm without splints. Such a result indicated that radium therapy presented the nearest approach to a specific therapeutic measure in cancer. In practice, however, the action of radium had its limitations, and the results obtained thus far varied with the size and location of the tumor. Even the most powerful *x*-ray machines and tubes, developed in this country and abroad, still must leave the distance between the *x*-ray tube and the tumor too great for efficient action. The new method of radium therapy developed recently by Duane obviated to a great extent the difficulties created both by the size and location of the tumor. It consisted in the use of buried radium emanation tubes. Each minute glass tube contained not more than about three millicuries. A sufficient number of the tubes was buried in the tumor to cover its whole mass and it was left there permanently. But even with the best methods available only a small percentage of cancer patients had thus far been benefited by radium and roentgen therapy, and the same held true, in reality, for surgery as well. The percentage of operable cases as related to the whole number of cancer patients was small. Just as small was the percentage of cases adapted to ray therapy at the time when the cases were referred for treatment. The remedy was self-evident and consisted in correct correlations between surgery and radiotherapy. A new orientation must be created in the surgery of cancer. Surgery need not be as radical as heretofore since radiotherapy employed before and after operation could take care of the small remnants of the tumor left behind in the operating field. As a result a greater percentage of cancer patients would be operated upon and treated, and a greater ultimate percentage of successful cases would be recorded.

Dr. JOSEPH A. BLAKE, after expressing his appreciation of the papers, said he had done little work on carcinoma of the rectum in recent years and had published little on this subject. At one time he had operated upon some fourteen or fifteen cases of cancer of the rectum by the same procedure and the results were quite encouraging. The operations were done some eight or nine years ago and quite a few of the patients were still living; some of them he had seen within the last year. They were all operated upon by a rather thorough operation. There was no mortality in the series, and although the operations were extensive, the fact that there was no mortality, might be attributed, Dr. Blake believed, to the nature of the operation, which was a combined operation which permitted one to determine the exact extent of the local growth and the involvement of the portal and lymphatic systems. This was the reason, as Dr. Lynch had brought out, why the abdominal operation should be done, because it was entirely wrong to submit the patient to such a dangerous operation as excision of the rectum if there were extensions or metastases in the vital organs. The operation he had used was as follows: A median incision was made and the growth clamped with two clamps at the lowest point consistent with safety. The gut was divided between the clamps with the cautery, the proximal clamp having been passed through a muscle splitting incision which was to be the future colostomy; the end of the gut was drawn out onto the abdomen and the clamp left on. This was all the attention paid to the colostomy. The lower segment was freed from above and removed by the operator or an assistant, working from below, with the patient in the lithotomy position. The entire bowel was removed leaving a clean wound, the anus having been sewed up and cauterized to prevent infection. There being a perfectly clean wound the results so far as the immediate mortality was concerned were good. The later results were also good on account of the fact that no attempt was made to conserve any part of the rectum for future anastomosis. If the carcinoma as located in the sigmoid then operation was performed by anastomosis, but in the series of cases in which the carcinoma was in the rectum the operation was complete removal of the rectum. Dr. Blake said it was his belief, when the sphincter had to be removed, that an inguinal colostomy was more efficient that an artificial anus. Then we come to a class of patients in whom there is recurrence after operation. The patient who had a recurrence and eventually came to colostomy, he believed, would have had a longer and better life if colostomy had been originally instituted and the parts in which the recurrence had taken place were not subjected to the irritation of fecal flow and not subjected to the infection that occurred with cancer in this region. The patient did not suffer pain, was more comfortable, and his life was prolonged. Then in some cases in which there was a recurrence of the growth, if the patient was referred to the radiologist he had a better opportunity of helping the patient and prolonging life if he was not embarrassed by the fecal current passing over the radialized tissues. Dr. Levin had spoken of connective tissue formation following the use of radium. He believed this was an expression of tissue repair and showed how much the cancer cells were broken down and destroyed. If infection occurred in addition to this destruction of the growth a much more violent reaction occurred and there was much more pain and discomfort. In regard to the general radium treatment of cancer, it seemed to him to be fairly rational when growths were accessible to radium and inoperable from the standpoint of removal by surgery that a certain procedure should be inaugurated. This should be to isolate the tumor by operation as far as possible, and thus prevent extension. For instance, one often saw a new growth in the mouth treated by radium without attention to lymphatic extensions down the neck. It seemed to him reasonable to block this path of transmission or extension by a thorough radical extirpation of the lymphatic channels and nodes of the neck, thus leaving the growth without means of extension to be treated by radium. As to the treatment of cancer of the rectum by radium, Dr. Blake said he had been interested in watching the progress of

several cases. One patient, probably one of the first treated by radium for carcinoma of the rectum, when he came under his care about eleven years ago had no discernible growth. His history was that he had had a growth diagnosed by a reputable surgeon, that it was examined histologically and reported cancer, and that the patient had been treated with radium. When Dr. Blake saw him he had had hemorrhages from the intestine, but there was no growth as far as the sigmoidoscope reached. Another patient had a circumferential carcinoma of the rectum invading the perirectal tissues and obviously inoperable. He also had myocarditis, and an uncompensated valvular lesion. He was treated with radium and in two months had only a small nodule, no pain, no obstruction, no hemorrhages. His life had at least been prolonged if he had not been cured.

Dr. A. A. BERG stated that there had been more changes in the surgical treatment of carcinoma of the rectum in the last decade than in any other form of cancer. He could recall when they began to use the Kraske operation, which they had now given over almost altogether. Our modern methods as compared with the Kraske operation were about as different as day was from night. Surgery in carcinoma of the rectum had a great deal to promise the patient, not only in prolongation of life but in radical cure. He thought 26 per cent. of cures was not at all an exaggeration, for cancer of the rectum was not a malignant form of cancer. He took it from what Dr. Lynch and Dr. Blake had said that there operations had been done in one stage. Colostomy, excision, and final closure were lengthy, complicated, and did not produce as large a percentage of radical cures as had been expected and as were being obtained by the one stage method. A preliminary colostomy was only indicated where there were severe obstructive symptoms. The abdominal and perineal operations were greatly to be desired types of operation for the radical cure of carcinoma of the rectum. In reference to the incision and mobilization of the capsule of the rectum, it should be emphasized that the capsule should not be entered, and the rectum should be removed with the cellular tissue intact. This could scarcely be done by the perineal operation, but it could be done safely, rapidly, and successfully by the higher operation. In the lower carcinomas complete excision and amputation of the rectum should be done. As we continued to make progress and to change our technique to meet new conditions, there would be fewer recurrences and we would take exception to the former attitude of considering the abdominal route as a *noli me tangere*. The mortality of the abdominal operation was low; it could be done as a one stage operation, and resulted in a permanent cure, with good functional results in the majority of cases.

Stated Meeting, Held May 23, 1921.

THE PRESIDENT, DR. GEORGE GRAY WARD, JR., IN THE CHAIR.

Symposium on Modern Methods for the Prevention of Diphtheria.

Preparation of Mixtures of Diphtheria Toxin-Antitoxin.—Dr. EDWIN J. BANZHAF read this paper, in which he said that in preparing the toxin-antitoxin mixture for active immunization against diphtheria, it was essential to have diphtheria toxin of very high potency. The toxin they employed had a minimum lethal dose of 0.002 c.c. to 0.0007 c.c. The advantage of using such highly potent toxins was that they might be diluted with salt solution to the toxic strength actually required, lessening in this way the concentration of other substances which gave rise to local and constitutional reactions. The most important factor in these reactions was the bacillary substance which could not be eliminated by any method at present available. At best one could only minimize the reactions in those who were hypersensitive to these substances, by using only highly potent toxins which would allow of dilution. The toxin, when freshly prepared, was unstable and deteriorated rapidly at first. After six months the toxin approached a relative stability and could then be used for the preparation of the toxin-antitoxin mixture. Several lots of such toxin were mixed to give a total of about 60 litres. The L plus dose was then determined. The L plus dose was that amount of toxin which, when added to one unit of antitoxin, would give a mixture which when injected into a 250 gram guinea pig would cause death on the fourth day. The toxins used contain from 4 to 6 L plus doses per c.c. As the convenient immunizing dose was set at 1 c.c. for each injection, it was desirable to have all the preparations of toxin-antitoxin mixtures standardized to contain the same immunizing value; they theretore set the standard at 5 L plus per c.c. Each mixture of toxin was consequently diluted with sterile salt solution, containing the required amount of preservative, to the above mentioned standard. An aged standardized antitoxin was than added to the toxin, one unit of antitoxin for each L plus. The mixture was therefore theoretically toxic. The use of this proportion insured against a possible over-neutralization. If the mixture was too toxic more antitoxin could always be added. The calculated amount of antitoxin to be used was greatly diluted and added slowly, under aseptic precautions, to the toxin which was constantly agitated to insure a complete mixture. This was then allowed to stand for three hours when it was tested out on guinea pigs. For the preliminary test two groups of guinea pigs were employed. To each of one group was given 1 c.c.; to each of the second, 5 c.c. The injections were made subcutaneously. If the mixture was properly adjusted the guinea pigs receiving 5 c.c. would die acutely, whereas those receiving 1 c.c. would show no immediate effect but would develop paralysis after two weeks. If the mixture was too toxic more antitoxin was added until the above condition was reached. The mixture was then filtered through a Berkfeld filter and stored in a refrigerator for stabilizing. The mixture was later retested and any necessary adjustments made. Such a mixture retained practically its full immunizing power for at least one year.

The Duration of Active Immunity after Injections of Diphtheria Toxin-Antitoxin.—Dr. MAY C. SCHROEDER made this contribution, in which she said that the practical value of the toxin-antitoxin immunizing injections depended upon the harmlessness of the injections, the proportion of the susceptibles who responded and became immune, and finally the duration of the immunity. They had decided that the most favorable means of determining the duration of immunity was to seek institutions where children were held for a number of years. Dr. Zingher and the writer had picked out a number of institutions and had followed the children from year to year. Five and one-half years had elapsed since the children in the first institution were treated. They had also tested over 4000 inmates of the State Institution for the Insane, in order to obtain results on a group of people likely to remain located indefinitely. Tables showing the results of repeated tests in the same children following immunization showed that when once antitoxin developed it was quite or almost as persistent as in those who developed it naturally. It had been shown in their work that active immunity could not be produced in young infants by toxin-antitoxin injections owing to the inhibitive effect of the passive immunity derived from the mother. This passive immunity was lost later. Consequently toxin-antitoxin could be depended upon to act effectually only after the age of six months. During the past two years fully 50,000 children attending the public schools of Brooklyn had been Schick tested and immunized under the writer's personal supervision. During the past month they had been retesting the children who had been immunized. The results showed that in 90 per cent. of the children immunity had persisted until the present time. This meant that at least 90 per cent. of the sickness and deaths from diphtheria could be prevented.

The Schick Test and Active Immunization with Toxin-Antitoxin in Private Practice.—Dr. DEVER S. BYARD presented this communication, in which he stated that there were approximately 500,000 children in this city of an age group susceptible to diphtheria, who were some or all time private patients. To make

them safe subjects in the community and to secure for them an immunity to diphtheria identical with that conferred through public agencies, was the outstanding opportunity and responsibility of the private physician. Protective inoculation against diphtheria must have, soon would have, its accepted household place with the present required vaccination against smallpox. During the 2½ years ending March 31, 1921, of all cases of diphtheria in New York City, an average of over 78 per cent. occurred in and were treated in private homes. In 1920, there were 10,386 cases thus treated. Such statistics emphasized the outstanding importance of private physicians—pediatrists and practitioners—in all matters looking to diphtheria control in the community. Dr. Byard described the results of a survey of 192 families showing the response of the average parents and guardians to a new program of diphtheria prevention. Of these 192 families slightly over 15 per cent. refused cooperation, both in the Schick test and toxin-antitoxin prevention. Eighty-five per cent. accepted the program in whole or in part. In these 192 families, 388 children were included. Of 317 children receiving toxin-antitoxin, 286 were Schick tested at a date averaging seven months after inoculation. Of these 286 tested, 7 were susceptible and 5 were regarded as slightly or doubtfully positive. Of 299 children tested, accepting the combined results of early and later retesting by the Schick method, five, or 1.7 per cent. failed of immunity. In the Schick testing and retesting during the last year and a half for all the older subjects a control reaction was observed. This was important as a gauge of the degree of the frequently observed reactions due to protein. While no statistical value was claimed for these clinical observations, they did, however, attest large parental cooperation and the summaries closely approached the expectation of result of Schick test and toxin-antitoxin use, which the precise and extensive work of Dr. Park and Dr. Zingher had formulated. They particularly instanced the high susceptibility to diphtheria of groups of children in private families having average community contacts and exposure. The records of these children, over 50 per cent. of whom were under one year of age, confirmed the safety and expediency of the preventive measure. The high degree of conferred immunity warranted an urged, aggressive program. The responsibility was theirs. The public, sufficiently advised, would prudently cooperate in this undertaking which so importantly concerned it.

Diphtheria Preventive Work in the Public Schools of New York City.—Dr. ABRAHAM ZINGHER presented a comprehensive report describing the active campaign in diphtheria preventive work in the public and parochial schools of New York City. Between the end of February, 1921, and the end of the school year, they had applied the Schick test in 44 of the larger schools in Manhattan and Brooklyn and had tested over 52,000 children. Those who gave a positive or a positive combined reaction were injected with toxin-antitoxin. The results of the Schick test in these schools indicated that the socalled "natural immunity" depended to a large extent upon *contact immunity* developing after repeated exposures and mild infections with the diphtheria bacillus. The children of the more well-to-do classes of our population showed a much higher proportion of positive Schick reactions than did the children of the poorer classes. Relative segregation of the first, crowding and close contact of the second, probably accounted for these results. The factors of race and hereditary family tendency also seemed to influence considerably the development of natural immunity to diphtheria. Negative pseudoreactions were found in some schools in fully 20-25 per cent. of the children. These figures indicated that it was strongly advisable always to use the control test along with the Schick test in children over 5 years of age so as to identify accurately the children who showed a negative pseudoreaction and thus avoid giving them the injections of toxin-antitoxin. The results of the Schick retests which were made in the schools after two to five months indicated that it was better to wait six months or preferably longer before testing for the development of an active immunity after toxin-antitoxin inoculation. Two injections of toxin-antitoxin, even of a larger amount, did not give as good results as three injections of a smaller amount. The mixture should be under-neutralized and yet perfectly safe for the human being. Children under six months should not be injected with toxin-antitoxin, since 58 to 90 per cent. of them were immune and did not respond to these injections, as was shown when they were Schick tested later. *All children from six months to five years should be injected with toxin-antitoxin.* The omission of the Schick test in this age group was not of much consequence, as most of the children gave a positive reaction. A majority of these children could be reached in the homes, in milk stations, day nurseries, children's dispensaries, infant and orphan asylums, etc. To place the diphtheria preventive work in the public schools of a large city on a practical basis, it was advisable, for the present at least, to simplify it for the school physician by omitting the preliminary Schick test in the younger children and by immunizing all children of the incoming classes with toxin-antitoxin. No child should be pronounced immune to diphtheria until it gave a negative Schick reaction. The test should not be made until at least six months had elapsed after the injections of the toxin-antitoxin. School children in the grades above the incoming classes should have the Schick test and control test made before they were injected with toxin-antitoxin. Only reliable outfits for the Schick test and carefully prepared mixtures of toxin-antitoxin were of value in such preventive diphtheria work. The Schick work in the public schools was carried out under the direction of Dr. William H. Park and in cooperation with Drs. S. J. Baker, Jacob Sobel, and J. Blumenthal of the Bureau of Child Hygiene, and Dr. Louis I. Harris of the Bureau of Preventable Diseases of the Department of Health; Dr. I. H. Goldberger of the Bureau of Educational Hygiene of the Department of Education, which was largely instrumental in gaining permission for them to do the work in the schools, and by the Manhattan Chapter of the American Red Cross, through Mr. George Bedinger, who was in charge of its Health Service Department, which had lent substantial financial support to the work.

Does a Negative Schick Test Indicate Present and Future Security from Diphtheria?—Dr. WILLIAM H. PARK made this contribution, in which he said that this question could only be properly answered by considering not only whether the amount of antitoxin in the body which was sufficient to neutralize the toxin injected for the Schick test was sufficient to prevent diphtheria, but also whether a negative test indicated this; that was whether there was apt to be error in the technique so that occasionally a negative outcome meant a faulty injection or an improperly standardized toxin rather than a neutralization by antitoxin present in the body. During the past eight years they had carefully investigated every case of suspected diphtheria occurring in children or adults who had given a negative Schick test. They had collected altogether 18 cases. Six of these they believed to be due to errors. On the other hand, they had met with two experiences in children and two in adults, all reported to have given negative Schick tests in which the development of exudative inflammation of the tonsils, or of the tonsils and lateral wall of the pharynx, required some other explanation. In the case of the two children the supposition was that these were cases of croupous tonsillitis and that the diphtheria bacilli were present without producing lesions. The other supposition was that while the children were ill with streptococcic tonsillitis the diphtheria bacilli present in their throats grew in the exudate, producing endotoxins and exotoxins, and these added slight diphtheritic lesions to those caused by the streptococci. The amount of antitoxin present would thus be conceived as too small in amount to prevent contact irritation but as sufficient to prevent general poisoning. It might be concluded that a negative Schick or a negative result from vaccination was a strong suggestion of immunity but not an absolute assurance. In both cases this uncertainty was because of doubt as to the potency of the product and the accuracy of the technique. In either case, a repetition of the inoculation

might be followed at times by a different result. Because of these facts it would be foolhardy to refuse to give a child antitoxin who had a history of a negative Schick test in the face of suspected diphtheria, just as it would be foolhardy to rely on a recent unsuccessful attempt at vaccination in the face of definite exposure to smallpox. Either improperly measured toxin or imperfect technique would probably prevent the development of the positive Schick reactions in susceptible persons. The failures were so few, however, that it was justifiable to consider that persons were in all probability immune who had a record of a carefully done negative Schick test. Careful investigation led to the belief that about 2 per cent. of the persons giving negative Schick tests did so because of error in technique. Where great care had been taken to have the toxin strength correct and the injection given strictly intracutaneously they had not discovered any errors.

Dr. LOUIS I. HARRIS said the community ought to be grateful to Dr. Park for having helped to establish the Schick test and the use of toxin-antitoxin on a firm basis with the aid of his devoted and loyal staff. In a promiscuous and crowded population, such as that of the city of New York, there were many diphtheria carriers and contact with them was inevitable. According to the estimates of Weaver, Hartley, Martin and others there was probably a total of from 160,000 to 200,000 diphtheria carriers in the city during the winter season. It was a marvel that we did not have a larger number of diphtheria casualties. While we might estimate the direct and immediate morbidity and mortality from diphtheria, who could tell to what extent diphtheria and its sequelæ were responsible for many of the ills of adult life. Because of its effect on the heart and kidneys, who could say how great a part diphtheria was playing in causing diseases of these organs which became manifest in adult life? Surely the problem of controlling diphtheria was enormous and the Schick test and toxin-antitoxin immunization bid fair to solve it. The present faith in the universal efficiency of the Schick test recalled the situation in respect to typhoid prophylaxis when antityphoid inoculation was first introduced. It was thought that it would be universally effective, but we learned in the war that there were exceptional cases in which typhoid inoculation failed to give immunity. The same mistakes should not be made in regard to the Schick test. We should be guarded in our promises of ability always to confer immunity. We should not instil the thought that the Schick test and toxin-antitoxin immunization offered a sure protection against diphtheria. A point brought out during the discussion, but not sufficiently stressed, was that if the Schick test were read too early a positive reaction might be overlooked. One could be sure of the reading only on the third, fourth or even fifth day after its administration. The work of Weaver and of Hartley and Martin and others brought the point out strikingly, how frequently diphtheria cultures taken to terminate quarantine in cases of diphtheria misled those who relied upon a single or even two negative cultures. He pointed out that we had been compelled to make an oblique attack upon diphtheria through the use of the Schick test and toxin-antitoxin, because the direct attack in terminating the carrier state had failed. If the people were to reach the full value of the Schick test and of active immunization against diphtheria, the cooperation of the medical profession was essential. They should remember that every physician if he were doing his full duty was an unofficial health officer. The medical profession should supplement and extend the work of the Health Department as Dr. Byard had done, even though they might not be able to do so on as large a scale. In that way only the frightful mortality from diphtheria could be controlled.

Dr. EVERETT W. GOULD said that these interesting and valuable papers had covered the scientific aspect of the subject so thoroughly that it seemed best to give the experience with the Schick test and the protection of susceptibles at St. Luke's Hospital. They had been relying upon the Schick test in all cases entering the hospital, both surgical and orthopedic as well as the medical cases. All those giving a negative Schick test were not immunized, while those giving a positive test were thoroughly immunized. Since this procedure had been adopted seven years ago, they had not had more than four cases of diphtheria in children developing among those who had previously shown a negative Schick reaction. Those cases were all given antitoxin and recovered. It was impossible to say whether these were true cases of dipntheria developing in children previously showing a negative Schick reaction or diphtheria carriers who had developed tonsillitis, or, more likely, were instances where the Schick reaction had been falsely reported as negative as a result of a mistake in the technique or in the interpretation of the reaction. He thought that the fact that only four cases of diphtheria developed among the hundreds and thousands who had been subjected to this test was an excellent argument in favor of this method. About five years ago a nurse had a Schick test made by a capable man and reported as negative. About four weeks later she developed a sore throat, which gave a negative culture, although clinically it resembled diphtheria. On account of the previous negative Schick no antitoxin was given. Two days later the nurse developed laryngeal diphtheria, but after large doses of antitoxin were administered she recovered. That was reported as a probable instance in which an individual with a negative Schick reaction developed diphtheria. Two years later, and again recently, she showed a slightly positive Schick. This meant undoubtedly that an error had originally been made in the test or in its interpretation. Last year Dr. Gould said they had a slight epidemic of diphtheria in a surgical ward, there being two cases in children and two cases in nurses. Careful investigation showed that one child had had its Schick test in 24 and 48 hours, but on the fifth day it was not read. He believed that if the test had been read on the fifth day it would have been found to be positive. They had frequently found that reading the reaction on the second and third day was not sufficient, it should be read also on the fourth day, or better even on the fifth. The second case of diphtheria occurred in a child whose Schick test was reported positive, but through some error the child had not been immunized. One of the nurses was subsequently found to have a mild positive Schick test; the other had a mild form of throat trouble, which subsided without antitoxin, and they thought that probably she was a carrier. From their experience they could say that they believed the Schick test to be a most dependable method of determining the susceptibility to diphtheria, and cases reported in which it had apparently failed were probably instances where errors had been made either in the technique of the case or in its interpretation. It was very easy for one unfamiliar with the details of the test to make such errors. All cases showing evidences of clinical diphtheria, even though credited with a negative Schick, should receive antitoxin for fear an error may have been made in the previous test. If a blood examination could be made to determine its antitoxin content in such a case the antitoxin might be withheld for a few hours to await the result, for there was, of course, no advantage in giving antitoxin to one who already had sufficient in his blood even though he had virulent germs in his throat.

Dr. JACOB SOBEL stated that his experience with the Schick test for the detection of diphtheria susceptibles and for the production of active immunity in these susceptibles by the administration of toxin-antitoxin had been derived from private practice and from his rather extensive supervision of this work for the Bureau of Child Hygiene of the Department of Health, which was charged with the administrative health control of children from birth up to the age of sixteen years. Dr. Park and his group of pioneer workers in this field had told us that within the past twenty-five years there had been a reduction in the mortality in this disease of from 150 to 22 per 100,000 of the population. During the last ten years, however, the mortality and morbidity from diphtheria had remained practically stationary. It seemed as if we had reached the limit of possibilities of control by means of the methods at our disposal, namely, the use of antitoxin

therapeutically and prophylactically, isolation, quarantine, hygienic and sanitary measures, etc. Dr. Sobel stated that his remarks would be confined to the clinical, administrative, and educational aspects of the subject, inasmuch as the papers had taken up the scientific side so thoroughly. There were two outstanding reasons why further progress in the control of diphtheria had been limited. The first was because of the fact that one-half or more of the cases of diphtheria gave no history of having been exposed to active or convalescent cases of this disease, and secondly, because of a large susceptible population. Why, then, if one or more of the cases did not come in contact with active or convalescent cases of this disease was there so much diphtheria? It seemed to him that the reason for this was three-fold: First, carriers; second, missed cases; third, nasal diphtheria. Dr. Harris had spoken of the large number of carriers extant in this community. It had been estimated that at certain seasons of the year, one to two per cent. of the population of approximately six million harbored diphtheria bacilli of varying degrees of virulence. This, however, did not cover the situation entirely, because there was in New York City a daily floating population of approximately 500,000, which had a similar percentage of diphtheria carriers. Furthermore, from studies conducted by the Bureau of Child Hygiene and from the contributions of Weaver and of Moss and his coworkers, in a recent issue of the Johns Hopkins Bulletin, it was shown that among children the percentage of carriers was from 4 to 8 per cent. Since children came in contact more generally with those of their own kind and age, the significance of this high percentage of carriers among them was evident. By the missed cases he meant that large group of sore throats, either angina or follicular tonsillitis, which were either true cases of diphtheria or carriers, and which were frequently unknown, unsuspected, undiagnosed, and untreated, and which, by mingling with the general population, disseminated diphtheria. It was this type of cases that explained what Dr. Zingher referred to, namely, the larger percentage of positive "Schicks" among children of the well-to-do, or, in the better schools, socalled, as well as the larger number of susceptible children in rural districts and rural schools. Closer association and more intimate contact among the poorer element resulted in the greater spread of the diphtheria bacilli with resultant establishment of artificial immunity. The third source of infection was the mild cases of diphtheria. Dr. Sobel said he was convinced that these cases were of far greater frequency than was generally known or admitted. The severe cases were readily recognized, isolated and treated, but the mild cases, those with muco-sanguinous discharge, slight, moderate, or no temperature, submaxillary adenitis, etc., very often escaped detection and literally poured out diphtheria bacilli. These cases were not infrequently looked upon as "cold in the nose" and by association with others spread the disease. Add to these three important sources of contagion the large percentage of susceptibles, and the need for the Schick test and the production of active immunity became apparent. We had learned through Dr. Park's school that the greatest number of susceptibles were found among children between the ages of one and two years; or, as a group, in children of the pre-school age, from two to six years. Sixty per cent. of the susceptibles were found at this age period. Why then was the problem first attacked among the children of school age? In the public and other schools there were approximately one million children readily accessible easily supervised, easily controlled, easily followed up. Among this number there were 25 to 30 per cent. susceptible to diphtheria. This percentage was even higher for the kindergarten and children admitted to school for the first time. It was felt that if this 25 or 30 per cent. were immunized just that number of potential cases of diphtheria would be controlled and removed as a source of community danger, and thus younger children of the family would be protected. Through the school authorities and the school children, a vast amount of educational propaganda could be instituted. Most important of all was the fact that through the work in the schools, the public could be taught. The public must be educated up to all types of preventive health work. They were not so ready to accept preventive measures which were associated with the injection of heterogeneous substances into the body. They felt that the public would learn through the school children that the Schick test was harmless and that the injections of toxin-antitoxin were comparatively free from ill effects, they would gain confidence in the procedure, and that then, as a matter of course, they would be ready and willing to have it applied to the large susceptible element of the population—the children of pre-school age.

Mr. GEORGE R. BEDINGER stated that he represented the New York Chapter of the American Red Cross, and being a layman felt doubly honored in being able to say a few words. The starting point of all the work of the American Red Cross was that public health was the job of public authorities in the long run. The work of the Red Cross was simply to tie together the activities of other agencies in the community and to place them on a basis where they could offer a more coherent and effective organization for work along public health lines. The majority of their activities were in the nature of a demonstration, and whenever the public health authorities came to regard these demonstrations as practical the American Red Cross welcomed that time and were glad to have the public health authorities take over such activities. The reason they had become interested in the application of the Schick test was because Mr. Homer Folks and Dr. Copeland had asked them to help to meet an emergency occasioned by the fact that the Board of Estimate refused to make an appropriation which would enable the Department of Health to carry out the work of Schick testing and immunizing public school children against diphtheria. They saw in the Schick test the opportunity for doing a great work in the community, and it had given them great pleasure to be associated with Dr. Park and his associates in this activity. Dr. Park presented the subject to them and told them that he needed money and personnel to carry on the work necessary to demonstrate what could be done in the control of diphtheria. It had been a great pleasure to be associated with Dr. Zingher in the practical work among the school children. He hoped Dr. Zingher would pardon him if he attempted to make one point a little clearer. Dr. Zingher had mentioned that the Red Cross was going to establish a health center in East Harlem. He wished to say that the American Red Cross was only one of the agencies interested in this project. The Red Cross was going to provide a building and personnel, and other organizations in that locality would work with them in these headquarters, the headquarters being merely the Red Cross contribution to the work.

Dr. ZINGHER invited those in the audience who might wish to see a demonstration of the method used in making the Schick test to remain after the meeting, when he gave a practical demonstration.

The Plague at Marseilles in 1720-1.—Boinet calls attention to the very severe outbreak of plague at this port two centuries ago. The first case was reported June 1, 1720, the patient having reached town in a vessel. The disease was believed to have spread through the merchandise brought by the ship in question. During the following September the death rate went as high as 1,000 daily.—*Gazette des Hôpitaux.*

Bismuth in Syphilis and Trypanoses.—Sazerac and Levaditi have ascertained that a double salt of bismuth, the tartrate of bismuth and potassium, has an undoubted curative power over rabbit syphilis and the spontaneous spirochetosis of that animal. In the trypanosis known as nagana this property is less marked. In other words, bismuth possesses powers akin to those of arsenic and antimony in protozoan diseases.—*La Presse Médicale.*

Temperature of Epileptics.—Hartenberg has found both subnormal and supernormal temperatures in the intervals between seizures although in the majority there is no change from the normal. In some cases the evening temperature was so high as to suggest tuberculosis. In a few instances the temperature was highest in the morning.—*Journal de Médicine de Paris.*

HUMAN READJUSTMENT.
OR
COORDINATION OF STRUCTURE AND FUNCTION IN THE ORGANISM AS A WHOLE.*

AN APPEAL FOR THE EMPLOYMENT OF PRINCIPLES WHICH GUIDE ORTHOPEDIC SURGEONS AND ARE OF EQUAL VALUE FOR INTERNISTS.

BY J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

PROFESSOR OF PHYSICAL THERAPEUTICS AND DIETETICS, MEDICAL DEPARTMENT, TEMPLE UNIVERSITY.

THE reestablishment of health involves much more than the use of any scheme of medication, dietetics, suggestion, or of any other single means of remediation. When one group of major needs is supplied, it often happens that the organism can and does then recover equilibrium. When, however, this happy consummation does ensue, the problem is shown to have been a simple one; the chief handicap having been removed, the urgent requirements were met and recovery followed.

Man is a vitalized mechanism endowed with rare and varied self-regulative energies, defense reactions, powers for self-adjustment, to meet the needs of admirably designed, elaborated, and balanced structures. The majority of disorders require for their radical reestablishment that adequate attention be given to many accessory, collateral, or subsidiary disabilities or maladjustments, otherwise dissatisfaction may ensue.

Guided reintegration is thereupon needed, an intelligent bringing to a focus and putting to use all factors of remediation in order to achieve a relative norm of vigor, and of balanced consciousness.

Disorder or disease is in no single instance alone; it is always complex. Whatever anomalous states, latent weaknesses, or developmental faults exist, they must be reckoned with in the accounting.†

We must first learn to appraise conditions as they are and the due proportion between primary and acquired defects. The effects of disorder or disease, of acquired inadequacies, of minor deformations, of anomalies in structure, in reflex circuits, of ancient "insults," form a complex group of problems. Many of these are due to wrong habits, omissions, commissions, and commotions. Some or other such handicaps are invariably present in varying form or degree—but there they are, and to ignore any significant one of them is to invite disappointment, delay or defeat. These effects of previous disturbances—notably the less obvious ones—deserve more attention than they get, from the standpoint of readjustments of structure, of function, and also of consciousness. To omit a full, practical evaluation of these residua, whether obvious or determinable or rationally inferable, often nullifies our best laid plans. Hence attention is here asked to certain principles gleaned from the orthopedic surgeons. These when viewed in their due proportions should meet acceptance from every form of medical adviser, especially that most useful of men, the general practitioner.

Terminology.—Let me ask consideration for a few descriptive terms which should aid in simplifying concepts so soon as they become familiar. We must come to agreement on definitions which define, and words which describe and do not divert concepts.

I would use to describe the process of straightening out, or adjustment, the word "orthos" or upright—now a part of the word "orthopedic"—and substitute for "pedic" the word "kinetic," or the transition of energy potential into energy kinetic—energy in action, doing, performing, that is, actual movement. Hence we may use the term "orthokinetic," restoring orderliness through one or other of the modalities of movement. These manifestations of movement, active or passive, in their infinite modalities, constitute the prime condition of livingness. The crux of reestablishment is to stabilize consciousness through conditioned or trained reflexes.

Two forms of consciousness exist, the cerebral and the cellular. With cerebral consciousness we are all very much at home, thanks to the prodigalities of the psychologists. With cellular consciousness we need especially to familiarize ourselves. It is not only on a full parity with the other, but all signs point toward a consciousness which resides in cells, structures, mechanisms, as being rich with undeveloped possibilities in every day exigencies. Orthopedic surgeons during the war have come to accept the imperative demand for greater conscious, purposive self direction of motor mechanisms—assisted volition—in the restoration of many wounds of joints, amputations, and from the start. Here we have mass demonstration of cellular consciousness in the functioning, doing, performing, employed in the work of rescue, restitution *ab initio* and without ceasing. This is kinesia (doing) as contrasted with akinesia (not doing) or rest.

A term is in use by the French, "bio-kinetic treat-

*Read at the annual meeting of the American Therapeutic Society, June 3 and 4, 1921.

†This was a dictum of that towering master in medicine and in artistic readjustment, S. Weir Mitchell.

ment," the adjustment of life (bion) through movements of the body (kinesis).*

The Objectives and Principles of Orthopedics or Orthokinetics.—Orthopedic procedures aim at the restoration of departures from the anatomical norm, including shape, conformation, posture, and functional correlationships (or adjustments) making for equipoise, symmetry, and harmonious movement. They are applicable equally to a large proportion of clinical or so-called medical or internal problems, and in particular where the element of mechanical disarrangement is prominent, or recognized as causative or contributory.

The problem becomes one of how to recognize and appraise the significance of the factors which produce such distresses as can be removed by readjustment (orthokinetics). The objective is to replace structures which may be found in positions of *disadvantage* (thereby inducing the disability) into those of *advantage*. For example: Note the paramount significance of the reciprocal action and reaction of the overlying structures and the organs or viscera they enfold and protect; (1) the chest which contains the lungs, heart, and primary vessels; (2) the trunk and pelvis, containing the digestive, elaborative, and procreative organs; (3) the big muscle masses, static, locomotive, and shoulder girdle as oxygen elaborators; and (4) the accessory and supplemental action and reaction of these upon the well being of the special sense organs, the brain and the organism as a whole.

This repositioning includes the means of relieving the disability or even of reestablishing the organism in its entirety.

A review of disadvantageous attitudes, both structural and functional, motor or static correlationships, will reveal the baneful resultants of long antecedent structural anomalies or functional disorders which have produced the element of stress. Among these are: undue or protracted pulls or twists or compressions on muscles, on fibrous structures, on tendon sheaths, on nerves, on venous and lymph channels, also interferences with the economic distribution of static forces whereby disordered, over-tense, relaxed or painful states are brought about, such as follow disturbances in the nicety of poise. The reflexes being disordered (shown by tonic spasm, cramp, or anomalous attitudes of structures), the expenditure of motor forces becomes so large as to simulate protracted weariness, fatigue. Hence arise tonic spasms, aches, transferred pains, often lameness. These may, and constantly do, produce in acute conditions added distresses which, not being recognized, become merged into the clinical picture already formed, as merely a part of the original or more obvious disability.

Contributing factors to be considered are: protracted weariness, fatigue, or stress passing on to strain, exhaustion or functional commotion. These may arise long before the element of pathogenicity brings about changes in structure, which may be regarded as pathologic.

*In this connection it may be interesting to mention a yet longer but eminently descriptive word to visualize the whole round of bringing about orderliness, suggested to me by Dr. R. Tunstall Taylor, "orthobiokenetics." This may well describe the reestablishment of orderliness in the whole cycle of life processes.

Among earlier or temporary changes readily observable are: tonic protective muscle spasm, depletion or misdirection of forces being expended through loss of the automatic adjustabilities of the reflexes. The action of a disturbed reflex is shown in both passive and active phases. There is also the negative phase during which the mechanism is in repose and ready to perform. During this negative or resting phase the creature is, of course, not conscious of the reflex tonus. Whenever something arouses a hypersensitive reflex, howsoever little, the active phase is set in motion, keeps it too busy, force becomes expended over-actively. This stress, if not relieved, brings about an energy leak. This energy leak leads to weariness, to further stress and, when protracted sufficiently, to strain and finally to exhaustion, also serious perturbation of body or mind. Hence we have not only somatopathies but psychopathies of cognate significances.

Sensory mechanisms become likewise involved, first to so slight a degree as to be only subconsciously recognized as vague distress. Ultimately this distress rises above the threshold of consciousness and becomes pain. Also latent susceptibilities in the reflexes are to be reckoned with which no doubt vary in different individuals and also in the same individual under differing states or exigencies, but which impair harmonies of function.

Motor and sensory susceptibilities, or variants in susceptibility, serve as the background of disorders called functional. Also there must be considered divergencies in the status or tonus of the regulative mechanisms, the ductless glands, which through hyper or hypo-functioning lead to exhaustion and deteriorative states. Take for example the phenomena of the asthenias, the effects chiefly of adrenal hypofunction, also the well known effects of mild secondary hypothyroidism in producing asthenic states. Indeed, in order to interpret rightly many of the underlying or background states requiring orthopedic (or orthokinetic) readjustment, it is necessary to be familiar with, or consult an expert in, hemadenology (or endocrinology). A familiar example of this is defective bone growth, incompetence in ligament, tendon, etc., (hypothymus or hypopituitary), noticeable in such disabilities as weak foot arches.

Consideration must be taken of the fact that disordered states often fail to respond to perfectly correct attempts at orthokinetic (readjustive or orthopedic) relief, for the reason that equilibrium in circulatory and reflex arcs is temporarily impaired. For example: In headache which is capable of being caused by so varied a group of origins, each an acute or subacute state, remedial pressure, such as manipulations made over the posterior occipital nerves, often fails to soothe as it ordinarily does; it may indeed aggravate. So also of backache due to most divertified causes, direct and collateral.*

It should be noted that in order to do justice to the resources of orthokinetics (or orthopedics) in diagnosis or treatment, a fair familiarity must be had with many unfamiliar sources of gross func-

*See article by author, "Backache or Tenderness," *Int. Clinics*, Vol 1. Series 29, 1919. Also "Fibromyositis," MEDICAL RECORD, June 28, 1919. Also reproduced in the *Lancet*, Nov. 29, 1919.

tional disequilibrium. Next we should consider in connection with reflex regulation the various cycles of energizing, the cardiovascular-renal system and its regulation,* the respiratory, the genito-urinary, the digestive and metabolic (peristalsis being the chief motor factor); the special senses (in which reflexopathies are often paramount), and last, but not least, the finer, as well as the gross, motor mechanisms.

Note the effect of an unrealized, often unremembered, over-sudden action of muscles, in causing agonizing pains. Example: an individual who is muscularly powerful, but long has been sedentary, slips on the ice, automatically makes an immense effort to recover balance, succeeds, then for two or three days suffers excruciating pains due to fibromyositic strain, but the disorder is suspected of being something quite different. So of any extraordinary or unusual muscular efforts. The alarm is often quite pathetic, almost ridiculous, yet eminently real. Almost any form of trauma, displacement, "subluxation," etc., may be incriminated.

To be kept in mind too are the manifold effects of slight arthritides, irritations, often merely metabolic, affecting the joints of the backbone, the rib insertions, and the arthroses, amphiarthroses, and other articulations. Spondylitis has been shown by Vanderhoof (of Richmond, Va.) to be a relatively frequent but a rarely recognized source of much confusion.

Then I may mention the large and varied factor of posture (attitude) faults. Self-acquired or posture deformations may be visualized as due to such compensatory adaptations as the body is impelled to make by reason of effects (chiefly sensory) of protracted irritation whereby functional equipoise in static as well as motor mechanisms is disturbed. They may also ensue upon traumata of less or more severity. All these practically constitute "medical orthopedics" or orthokinetics.

Post-traumatic or post-operative orthopedics (or orthokinetics) is another matter; differing both as to kind and degree. A large proportion of these lamenesses or deformations arising primarily in self-acquired minor traumata or distortions or disfigurements may be so mild as to be scarcely noticeable and only to be demonstrated by expert observation or palpation. Many require little more than replacement by passive (manual) or by actively directed effort or movement remedies (kinesitherapy). Few conditions, comparatively, need severing of tissues (surgical interference), or complete fixation, or immobilization by apparatus.†

Moreover many, indeed a large proportion of lamenesses, disabilities, or deformations are due to tonic spasm, to local exhaustion, to disturbed sensory reactions, to pain reflexes, and disappear upon kinesigenic regulation of activities, especially after attention.

*See article by author, "Cardiovascular-Renal Regulation, Remarks on Certain Practical Devices or Processes Useful for Conservation and Reconstruction of Cardiopathic Patients," *Boston Medical and Surgical Journal*, October 9, 1919.

†Todd, Clinical Lectures on Paralysis, quoted by Kouindjy; and also Kouindjy, Pierre, "Le Traitement Hemiplégique," etc., *Arch. Neurologique*, 1900; Gilles de la Tourette, *Iconog. de la Salpêtrière*, 1897; also Kouindjy and Stragness, "Physiotherapy," C. V. Moseby & Co., St. Louis.

localized rest (akinesia), or by suggestion, voluntary relaxation by precise direction, by regulation of "nervousness" (psychomotor or anxiety hypertension), by tactful guidance, by subtlety, such as diversion of attention, and by substitution of energies. Hence the mind equally demands adjustment, compensatory and regulatory procedures, mental readjustment (or psycho-orthokinetics). To secure the mind and body (psychophysical) equipoise necessary it is my experience that soothing touches, tactile suggestions, or deep firm pressures are needed to supplement any mental suggestions; usually both are required.

As to that field to which we might apply the term "medical orthopedia" (Dubois), or let us say, medical orthokinesia, the straightening out of function by means of medication, drugs, biologic or serogenic remedies, vaccines, serums, etc., the subject is so large as to embrace the whole domain of internal medicine and its abundant resources. It is here merely referred to.*

Body defenses are to be studied in accord with the status of reality, of the individual as he is found; that is, his original, acquired, depleted, or deteriorated reactions. My personal inclinations are toward determining how body defects may be set in order from a mechanistic standpoint. It matters less how these deformations or maladjustments have been acquired, and what their extent may be, than it does as to their forms and manifestations and relievability. Hence the nutritive status always looms large and demands primary attention. Each clinician has his "flair," his point of view, his plan of remediation.

All roads, however, lead to Rome—the one goal being constitutional rehabilitation, restitution to the norm, or a relative norm. Through special studies of the ductless glands, the internal secretions, as a pupil of Sajous, I find many problems yield by using the light shed by a study of these great autoregulative governors. These glandular functions are capable of partial regulation by means of the several forms of orthopedia (orthokinetics).

Man, after all said and done, is a sentient mechanism with immense powers of automatic adjustment, of tending to return spontaneously to equilibrium. Man is exceedingly sensitive, yet capable of large self-regulation, and to a great extent, of self-repair, whenever favorable conditions are supplied. None the less is he a mass of static, mobile, interacting motor and psychomotor mechanisms, among which are: framework, muscles, connective tissue, ligaments, joints, tubes, fluids, containers, pumps, distributing channels, reflexes, bellows, gases, cells, reservoirs and regulators of energy.

Man being a sentient mechanism we must always reckon practically with the status of the "spirit," the mind, the psyche. When the psychogenic status is pretty well grasped, gauged, and the internal processes, biochemical, nutritive, and respiratory, are fairly assessed, it seems to me we are only then in a position to give equal attention to the make-up as a whole. Here the body as an engine for the generation and the transmission, transformation, application and elaboration of forces, deserves equal

*See article by author, "Supplemental Action in Reparative Measures, with Special Reference to Serogenic Remedies Reinforced Through Kinetogenic Agencies," *N. Y. Med. Jour.*, Sept. 18, 1920.

No more convenient or practical basis exists on which to appraise a clinical problem than by determining the question whether an individual is adequately "engined" or endowed with energy, also whether he be over- or under-engined—supplied with available power to run smoothly under normal and also under varied, trying, or disadvantageous conditions. Hence the topic of "Types of Men" is interesting in this connection.*

It is not safe to infer that an individual is equipped with just enough vigor to meet most exigencies. Perils ensue from disregarding the dangers of over-energizing (hyperdynamics) quite as much as from low energy content. The "human dynamo" exhibits excess pressure which is a defect of the structures against which pressure is exerted, they being inadequate to equalize the internal pressure. Here we have the analogue of hyperfunctioning of the ductless glands.

Military experiences have enriched us here in many directions, none more so than as to the nature, phenomena, and complex causation of shock. From this period we shall do well to appreciate the importance of appraising the shock value. This shock coefficient, reduced to simplest terms, is the capability of recovering functional equilibrium after stresses and strains, and is a province of medical orthopedics, or orthobiotics or orthokinetics.

Surgeons having experience in the war zone tell us that the treatment of all injuries comes practically within the strict interpretation of orthopedic remediation. The attention bestowed on the wounded or shocked (or cell commotioned) requires from the first special care in replacing the injured parts in the most favorable attitudes for advantageous mechanistics for functionation and equilibration, and in immobilization during the jars and jolts of transit and often after reaching the base hospital. Then throughout the treatment adjustment, adaptation, and compensation, also volition, self-direction, are constantly needed, not only to prevent subsequent deformity, but especially to defend the integrity of the parts and preserve their functional competence. While rest is one of the chief agencies in preventing, limiting, and curing local infection it must not be unduly prolonged. Voluntary movements are, however, frequently necessary from the outset as in joint injuries. (See the exploits of Willems in conserving joint traumatisms and infections.)

It is desirable that our students of medicine should be given particularized instruction and training in the principles of orthopedic (orthokinetic) prevention, remediation, and reconstruction. Much progress, so it seems to me, could be made by simplifying, by systematically grouping, all therapeutic agencies and measures. The fact is being made plainer every day that the principles on which these are based interdepend; that they interact helpfully.

We may profitably consider orthokinesis or orthokinetic adjustment and readjustment, as expanded to include the application of orthopedic principles to most, perhaps to all, problems of human disability, mental as well as structural.

*Stockard suggests that of the over-engined type the majority are hyperthyroid; of the placid, plump, pink type the majority are hypothyroid. This serves as a rough classification.

Psychogenic Factors to be Reckoned With.—Kinetogenic, orthokinetic, (or orthobiogenetic), principles or enterprises may be visualized under five heads which are interrelated, but not strictly separable, thus:

1. Developmental orthokinetics, primary or constructive kinesitherapy.

2. Mental or psychogenic, or educative, or regulative orthokinetics, the process of achieving conscious control of the body and mind as a unity.

3. Medical orthokinetics, including the selection and application of any or all the resources of internal medicine.

4. Manipulative orthopedia (kinetogenic or coadaptative remediation) by moulding, adapting, adjusting, freeing of limitations, of contractures, of adhesions, also passively moving (mobilization), stretching (traction), directing, in short passive and active hand compulsion within normal limits, etc. In all this the hand is shown to be the one perfect and ever available instrument.

5. Surgical orthopedia (orthokinetics), the use of supports, special apparatus, mechanical guides in action. (The strictly surgical, cutting, reattaching of parts, and the like, will be only referred to and regarded as a separate enterprise; also the removal of offending parts, whatever acts as an irritant or disturber of function.)

All clinical problems involve interactions of the mind and the body, and both require a certain degree of straightening out, readjustment, some more, some less; some by plain and simple means, others are so involved, complex, and obscure as to tax the abilities of the wisest experts. Also the body needs to be consciously and purposively controlled, to obey the will, and the will (volition, voluntariness) likewise deserves specific or particularized training.

In acute conditions of a trivial or transient nature the mental (psychogenic) element of disarrangement may not be noticeable, yet few persons when out of health escape misconceptions of their personal attitude toward their disorder. Any suffering one is better for counsel, suggestion, explanation, in order to be shown one's duty in its economic aspects, which is mental orthopedia or orthokinesia.

When any disorder becomes protracted or runs into chronicity the need for moral, mental or psychic, and kinetic orthopedia becomes urgent. Hence in a large group of morbid conditions five angles of approach or repair deserve attention, the developmental, the mental, the medical, the manipulative, and the surgical.

If the meager outline here offered does not interest the reader now, it should do so when the lessons of the war come to be better appreciated. Civilian and industrial injuries run each year into the millions deserving similar attention. Moreover the time—by all indications—has come when attention should turn in accord with my aims and those of better men who have taught along similar lines. Out of all the efforts made should emerge *an improved system of therapeutics* in which each and every reputable remedial and curative agency deserves a proportional degree of open-minded attention. The teachings of medical schools must take into full consideration the domain of biokinetics in

fitting young graduates to become better surgeon-physicians.

In lecturing, my personal endeavor has been to supply hints and recommendations which shall afford the most good with the least elaborate equipment. Only passing reference is made to those specialized domains of therapeutics such as electro-therapeutics, balneotherapeutics, radiotherapeutics, phototherapeutics, etc. They are left to experts in those arts. Attention is confined in teaching (chiefly) to such instrumentalities as any one either possesses or can readily obtain. One specification, or reservation, must be mentioned, somewhat rare and yet capable of attainment by effort and training. This is:

No one can either diagnose, or successfully treat, a case by externally applied measures who has not a fair equipment in, or knowledge, or appreciation of, the principles of physics; who can think in terms of mass, motion, hydraulics, pneumatics, mechanics, resistances, hyper- or hypo-tonus, tactile apperception, ponderability, in short of biophysics (or physicodynamics or orthobiotics).

He must at least cherish a respect for fundamental principles of hygiene based on facts and less on archaic, fragmentary, traditional beliefs, or sheer preferential methods. Candid gleanings of a life time have shown me that the "knowledge" (*sic!*) of hygienic principles employed by the majority of the profession is inadequate and vague. At this point the obvious losses which professional potential has suffered can be replaced and supplied by improved methods of readjusting the organism as a whole.

Diagnosis, general and particular, is obviously the first step; especially is it needful to learn and appraise the nature, extent, and form of manifestation of those instrumental causes on which depend the special kinds and degrees of disability or diseases demanding relief. The fact is, the chief obligation of the clinician is to repair the effects, the residua, of antecedent disorder or disease, and the best, often the only, means is by efficient readjustments.

Full clinical histories should, in every case, be secured. In order to proceed systematically and cover the whole purview, I have devised a "Preliminary History Blank, to be Filled Out by the Patient, the Family, or the Family Adviser." This blank is thorough and has been favorably commented on by reviewers and by those to whose criticism it has been submitted in manuscript. From this complete survey any outstanding points which appear should demand special exploration; the trends of evidence and in particular the local states which promise to reveal what it is important to know in order to institute treatment. This "Preliminary History Blank" can be had from the publishers, F. A. Davis Company, Philadelphia, Pa.

A familiarity is always desirable with the major principles of biophysics which, in my opinion, should be presented to the undergraduates with particularized applications to not only normal but abnormal states. Any physician should read over, once in so often, a primer on physics; this is a most enlightening procedure.*

Two courses of action should arise in the adviser's consciousness in times of need: one is to act promptly, guided by sound inferential interpretations: to supply such urgent help as experience suggests, a hit or miss, rule of thumb, rough and ready, but an efficient method, *e. g.*, to fix a watch we may listen to it, note disorders in action, may proceed to oil it, move its hands, shake it, and perhaps it will go. The second and more certain (or orthokinetic) method is to secure particularized information as to abnormal conditions and proceed to readjust them; in the matter of the watch, *e. g.*, to open it and, after carefully inspecting its mechanisms, to repair precisely what is found to be amiss.

Human reconstruction is the applying to an individual as he or she presents, at any age, or state, or stage, every reputable means obtainable (in particular biokinetic) to bring his or her coefficient of energy to such a degree of perfection as shall suffice either to: (*a*) raise whatsoever repair energies or survival values are available so as to reach as high a plane as the individual is capable of; (*b*) encourage and enhance the functional powers of all direct and contributory mechanisms in order that the organism as a whole shall respond as completely as possible to whatsoever corrective stimuli, or remediation, may be determined as essential. In brief, the major problem is to do the best for *the man affected by the disease*, and not confine attention to the *disease which has affected the man*.

The first steps are: a searching for, collecting, correlating, combining, and applying systematically and consistently any or all those agencies inclusive under personal hygiene, and in interpreting them in terms of development or structural and functional integrity to deal successfully with conditions of not only those in ordinary health, but also when states of ill health, and in particular the effects of disordered health (or unhealth) coexist.

Reconstructive remedial agencies (orthokinetic) are applied from without (*e. g.* by physical control or regulation) along with full cooperation with those meliorating agencies for psychogenic control (or mental regulation) inclusive under the term regulation of behavior.

The objective should always be plainly to avow and inculcate the need for, and to render the patient expert in, conscious purposive control, or in self-regulation of that kind, and to that degree, which shall meet the largest variety and number of exigencies.

Attention is commended to the curative value of those activities, in or out of health, which functionate on the sensorimotor level of nervous energy, as contrasted with those acting more prominently on the vegetative (or physicochemical) level on the one hand, and on the other the psychogenic or symbolic level. The proposition includes a summary of all

*Physics deals with molecular changes of matter. Mechanics deals with the laws of energy and motion. Psychology deals with the facts of consciousness; with classification and generalization of mental phenomena. Geometry deals with spatial facts. Chemistry deals with atomic combinations and mutations; different forms of matter. Physiology deals with processes going to make the equilibrium of organic life. Sociology deals with processes of social life, etc. Biology deals with the properties of matter and energy of living matter. The lines of demarkation between them are not defined; they interact. The admirable treatise on "Medical Physics," by John W. Draper, H. C. Lea & Sons, 1886, affords much help. This deserves to be revised and amplified to meet modern requirements.

these items and also that common denominator, a working knowledge of the unit of structure, the reflex circuits or activities, which are capable of affording much assistance in diagnosis, as well as indications and means of treatment.

In the balance of mental (psychomotor) attitude, or poise, or conscious control, there is also to be found the origin of, and key to, the phenomena of tension and overtension, of tonic muscle spasm, hence of exhaustion effects, of contracture, and of referred pains due to strains from maladjustments, wrong posture, static faults, defects in local tone, *e. g.*, excess motion (hypertonus or spasm) or in deficiency (hypotonus or relaxation). Here, among disturbances in this domain or level of nervous energizing, especially when following exhaustion, disorder, damage, or shock, do we encounter a variegated group of body and mind (psychophysical) symptoms whose significance too often escapes right interpretation because wrongly assessed.

The subject of suitable behavior, of self-regulation, of conscious control, taught in accord with expert knowledge of what is right and what is wrong to do, and how and why, I maintain, has as yet by no means received the clinical attention it merits.*

In the absence of expert knowledge of muscle education among physicians the bewildered laity turn to "professors of physical culture," *et id omne genus*, sometimes fortunately and again they fall upon varied forms of error. The regimental drill master does pretty well but he too often is of limited knowledge and crude experiences. The surgeon, especially the orthopedic surgeon, is equipped with much significant information and expertness, but he rarely gives due attention to the correlations of these proficiencies to problems of internal medicine.

As a matter of fact ample opportunity is thus afforded for the exercise of education or training in behavior by expert physicians, especially in restoring health and efficiency to the young men who may be rather below par or not up to standard. In particular is there urgent need for skillful reclamation services, restitution to the full norm, among all classes, groups, planes of society, young or old.

The tendency is to overlook any specialization developed along other lines than one's own, and to be content with our own purview, our range of experience or teaching. Every clinician should have some practical acquaintance with the leading principles of each and every specialty in order to make best selections.

Mental Readjustment or Reconstruction (Psychokinetics).—In every clinical problem the psychogenic or emotogenic factor enters; in some to a greater, in others to a less degree. This is particularly true after long stress and strain and in any protracted state of disability. Hence it is important, indeed necessary, for every surgeon, as well as physician, to possess some training in conditioned reflexes in psycho-pathology and psychotherapy.

The point of view here presented is of those conditions wherein mind and body together suffer from the effects of disordered feelings, ideas, and their misinterpretation. The mind is an essential attribute of the organism as a whole. The mental processes in and out of health are usually described from three points of view, viz.: feeling, willing, and doing; yet the whole may be graphically grouped under the will as a name for:

Behavior is the sum of actions of the body and mind under the control of a personality. The mind is at all times influential upon the body for better or for worse whenever, or especially wherever, there occur departures from health, from physiogenic and psychogenic poise. This is perhaps less noticeable in acute conditions; but is more pronounced in long standing, protracted or chronic disorders or diseases; also as manifested in their reactive and retroactive effects, direct and indirect. Experience leads to the inference that this department of therapeutics, that of:

Mind control, direction, conservation, and at times reconstruction enter as factors of extreme importance in readjusting an ailing person to his or her environment. This environment consists of two parts, that which the individual makes for himself from origins within, and that into which circumstances force him from without. Both of these exert peculiar effects on behavior by producing two kinds of reaction, physical and psycho-physical. The whole demands harmonizing. These psycho-reconstructive (psychokinetic) measures then are capable of making over a disorderly mind into an orderly, efficient, reliantly self-directive mind. In the process are evoked the:

Forces of common sense, well poised awareness of actual conditions in their normal associations and quantivalences, hope, cheerfulness, wholesome resolves to learn the rules of the game of life, and to play fair with one's self. The object is to induce the patient to see where he has stood in the hierarchy and determine clearly where he now wishes or determines to stand; to realize how essential it is that any problems, arising from departures from spontaneous health, require to be studied with frank cooperation and by guidance of the self-controlling forces and functions all along the interacting nervous levels, the vegetative, the sensori-motor, and the psychogenic.

Reflexes.—Closely associated is the subject of the reflexes, reflex circuits the unit or element of nervous function. By eliciting, for example, the reflexes, governing the functions of vegetative life through judiciously applied mechanical stimuli, there is at hand an important realm of medical as well as diagnostic endeavor. Reflex circuits can be both improved by training and modified or disordered by good or bad habits, and by disease. Some true reflexes can be modified advantageously by attention and conscious control; they may be brought to relative perfection; so also they may be vitiated by a number of somatic disorders and by pathological over-stimulation.

*Most physicians would have you believe they are competent to direct in all matters of behavior, of conduct, and even in so simple a one as hygiene, but if you put me on oath I should have difficulty in supporting this view!

Calcium Need of the Tuberculous.—Laufer and Lematte show that this demand is satisfied by from 1.75 to 2 gms. of alimentary calcium daily. This is easily obtained from milk and fresh cheese, for a pint of milk alone contains nearly one gram. It is, however, just as important for the patient to receive his daily ration of the other mineral constituents of the tissues.—*La Presse Médicale.*

THE TEACHING OF MEDICINE AND THERAPEUTICS TO UNDERGRADUATE STUDENTS.*

By THOMAS F. REILLY, M.D., F.A.C.P.,

NEW YORK.

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE, FORDHAM UNIVERSITY SCHOOL OF MEDICINE.

ASIDE from the increased requirements for entering on the study of medicine, the most noticeable change in medical education in this country within the past quarter of a century, has been the substitution of a large amount of clinical instruction in place of didactic and recitation work. That this has been a decided improvement on the older régime will be admitted by everyone. But that the pendulum has swung too far in the direction of clinical instruction, to the ultimate disadvantage of the student, will be a debatable question. If one visualizes the education of the young physician of a quarter of a century ago, it will be seen that the majority of such graduates stepped out of the medical school into general practice. Unless they were fitted by the instruction of a preceptor, or some practical experience in clinical ward work, such as is given at the present time, they were grossly incompetent. In England, where the system of clinical clerking had its birth, graduates commonly go out into general practice directly after leaving the medical school. The success of this method of clinical clerking in England is generally pointed out when this subject is under discussion.

In this country, however, at the present time an entirely different course is pursued by at least 98 per cent. of the graduates. Throughout the country, it may be said that it is an exception that a student fails to spend a period of at least one year as interne in a hospital. In many instances, two or three years are spent in this way and an abundant practical experience is gained. In view of this clinical experience, is it not germane to ask, whether it would not be better to concentrate the work in the medical school on the book-side of medicine, rather than to have the student spend, as he does in nearly all Class A schools, between sixty and seventy-five per cent. of his time in the senior year in clinical and ward work? From the standpoint of popularity with the student, there can be no question but that clinical instruction is the most favored form of instruction; he feels that he is learning without effort. In many instances, the clinical teacher likes it better because it is less onerous from a pedagogic standpoint. However, these reasons do not make it clear that clinical instruction is preferable. The objection will be raised that the student has, by the time he enters the senior year, completely covered the principles of medicine. If this were really so, and if he had grasped all of the essentials, there could not be any justifiable argument against the present arrangement, and this brings up the whole question as to the best methods of teaching the practice of medicine. Everyone has met students whose minds were so active and so receptive that, in the first instance, they grasped and retained practically everything given by recitation or by lecture. Such minds are few and far between. Fortunately, or unfortunately, many of these quickly climb the ladder of success and take their places as teachers of medicine. I say, possibly unfortunately, because the possessors of such minds, and they are inherited —not constructed by educational methods—expect the student to have mentalities like unto their own and expect him to grasp and retain all of the mental pabulum offered to him. Extended experience has made me feel that most of the fundamental facts and theories of medicine must be repeatedly driven into the average mind, before it is definitely fixed there. If one goes back and visualizes his own experiences as a medical student, I think that most of you will agree that your first reading or lecture, on any of the great problems in medicine, was mere jargon. This mental indigestion can be easily recognized, particularly in an attempt to study the anatomy and diseases of the nervous system, as well as the irregularities of the heart. This is true, to a greater or less degree, with all of the problems of medicine, but it is not so easily recognized. After going over such a subject a dozen times or more, order begins to grow out of chaos, and the facts become readily accessible to one's memory; even at mature age when one takes up some problem, such as, for instance, irregularities of the heart, mentioned above, it requires many repetitions of the facts before they can (as it were) be placed on one's finger tips. Of course, it is true that one occasionally meets a very clever student who recites brilliantly the first time he has studied a subject and who has this information readily accessible for years afterward, but he is the exception rather than the rule. It is not an uncommon experience in ordinary work, to find that such a student may recite or grasp a subject at the time of demonstration or recitation, and yet in from three to six months, when the identical question is put, his mind is for the most part a blank. If someone else has taught him this subject before, it may give a sense of satisfaction to the questioner and he, the examiner, may readily be excused if he says that the student was, unfortunately, not properly taught, but if it happens to be one whom he himself has taught, one has an opportunity to *swallow hard* and is not so filled with self approbation. The only practical solution for dealing with ordinary minds is continued repetition. The exponents of clinical instruction, as opposed to text-book instruction, maintain that by the presentation of the actual case, the subject is more firmly impressed upon the student's mind than is the text-book picture of the same. For the vast majority of minds, I do not think that anyone can seriously dispute this claim; on the other hand, each clinical case can represent only one phase of any illness, whereas the text-book picture covers many varieties of the disease. It is a practical impossibility to deal with more than a very few clinical entities in any single session, whereas the text-book recitations cover a large number of clinical pictures; furthermore, no matter how large the service may be, it is a physical impossibility to have any regular systematic sequence of cases. Unless this is done, many facts fall between and are lost. From a pedagogic standpoint, it is generally accepted that memory, certainly available memory, is better acquired when mental impressions are made on as many senses as possible;

*Read at the annual meeting of the American Therapeutic Society, June 3 and 4, 1921. (See page 475.)

in other words, a fact that comes to the mind through three senses is more apt to be fixed than one acquired through one sense, so that when one hears a subject discussed, writes the same subject, reads it over and over again, masticates it, digests it, and then puts it forth in the form of a recitation as his own mental product, which it is, he has a better detailed understanding of it, and it is more permanently fixed, than when he simply visualizes it in the shape of a clinical demonstration. It will be objected, that we visualize most of the incidents in life; even if this is granted, we do not visualize them in the sharp details, that we do the well repeated printed page. It must be granted, in any discussion of this subject, that there is no single process of mental fixation that will work for the minds of all students. To some minds, the clinical picture is a fixed and lasting impression; probably this preference depends on inherited racial traits, but for the average student, as I have seen him, I am convinced that book knowledge fixes a more accurate picture in his mind than clinical observation, provided he digests it and puts it forth in the shape of a recitation. Incidentally, I might remark that, in discussing this matter among teachers and practitioners, I have found that the surgeon usually answers, that he considered the clinical teaching superior to the book work, whereas the medical mind, in most instances, prefers the opposite.

I believe that the student's interest should be stimulated, to some degree, by seeing and looking after some clinical cases, from his second year in medicine, but this should not, as it is doing now, largely eliminate text-book recitation. The phase of the lecturer has justly been replaced in most schools. The number of teachers who can cover the ground by lecture, interestingly, without a clinical case in evidence, are admittedly few, and the text-books are so good and complete, that competition is out of the question, yet there is a field for some lecture work, just as there is a field for clinical instruction. With the passing of the lecturer one finds fewer idols in the shape of the old professor. If the whole subject of Materia Medica and Therapeutics of any text-book, were recited on year after year, there would not be so many practitioners taking up every new medical fad that is brought into their office by the detail man. As it is, dosage is seldom fixed in the student's mind; for that reason, he orders the proprietary, which he knows is not, in a general way, going to be toxic and he does not have to worry over dosage and incompatibility, and it saves him mental calculation. He does not stop to consider that the dosage is likely to be too small for any physiological effect, as long as the label states that the bottle contains drugs that he knows have therapeutic value and which, furthermore, states that they have a specific value for the type of case that he has under consideration. If he has his dosage fixed in his mind and readily available—as available as the months of the year—he is not apt to fall into this habit of allowing someone else to set the dosage. The study of dosage is a steady grind, that must be gone over and over by many frequent repetitions, and not by lecture or any kind of demonstration.

Recently, in a hospital examination of students, from various schools, I asked twenty-five men, what was the dose of fluid extract of Buchu and what was its principal use. It was surprising to find that 50 per cent. had never heard of the drug, some thinking it a patent medicine. If any standard text-book had been studied, and recited on from beginning to end, and repeated at least twice, such ignorance would be impossible. It is, particularly, the minor subjects that are apt to be missed in classes where the text-book is not made paramount. It will be objected that there is a certain amount of material in the text-books that is useless from a practical standpoint; this must be granted, yet any standard text-book covers the subject completely and makes the student familiar with the terms of the subject, so that, even though he forgets much of the total, the subjects and terms are not strangers to him when he sees or needs them, and at least he knows where to find the facts. These contentions pertain not only to the teaching of diagnosis, but to therapeutics as well. The knowledge of the action of drugs is largely a matter of memory. The experimental pharmacology is necessarily limited and the student must get the knowledg of drugs from many angles, but above all, from his text-books. The attempt to teach *all* therapeutics from a pharmacological standpoint entirely is a failure, and makes for an attitude of mind, that, unless things can be proven, they are useless; in other words, it causes loss of faith, unless positive proof is forthcoming. There are so many things in life that we must take on faith, that cannot be proved, that without it, life would be very uncomfortable. This attitude of mind is a perfectly proper one for the investigator, but it does not fit well in general practice; it is an attitude of mind that, once developed, is difficult to throw off. It is, undoubtedly, a large factor in inducing the medical student to prefer surgery and specialties, since his work can be seen and proven, definitely, without any question of faith or doubt. At the present time, I believe there is too much time spent on "fad lectures" and the minutiæ of the specialties, to the disadvantage of the major subjects. Some of this is doubtless due (1) to the frequently repeated lament of the older practitioners, who state that they were never taught such and such in their course; (2) to the enthusiasm of the specialist who thinks that the entire field of medicine revolves about his orb; (3) to the student who thinks he ought to be taught every new method that he reads in the journals and who feels that he could outline a medical course better than the Faculty. As it is, the curriculum is overcrowded in all Class A schools.

In summing up this discussion, we would like to point out that (1) Clinical instruction, in the three or four years of medicine, must constitute a large portion of the instruction of the student in medicine, who does not take a hospital interneship in a properly graded Class A hospital. (2) When a hospital interneship is taken, the time spent in medical school on clinical instruction may, for a *large* portion, be more profitably spent in text-book study, than in ward study. (3) Materia Medica and therapeutics, certainly the latter, are better fixed in the student's mind, in the medical school, by many repetitions of his text-book, than by a physiological demonstration. I am perfectly aware

of the fact that the views here expressed will be considered by many as being reactionary; anyone who runs counter to popular movements is thought to be reactionary, yet these views have been crystallized, after fifteen years of teaching, under both the text-book and clinical regimes.

34 WEST EIGHTY-EIGHTH STREET.

ON THE AIMS OF INTERNAL THERAPEUTICS.

BY L. RADCLIFFE GROTE, M.D.,

UNIVERSITY OF HALLE, GERMANY

EVERY pharmacological, but no less every physical influence upon the organism represents a sum of stimulations upon the cells of the body. By stimulation we here understand all influences upon the morphological and functional entity made up by the organized cells, whether this action be caused from without or from within—in the latter case from the functioning of the cell itself. A priori it may be said that, in principle, there must be two kinds of stimulations that are of different natures: first, those which are adapted to the chemical and structural organization, which can be termed, *adequate stimulations;* and secondly, those which, owing to their nature, cannot be adapted to the chemical and structural organization—*inadequate stimulations*. A cell can react upon a stimulus only when the latter corresponds to the cell's organization, which again is given by the constitution of the macroorganism. For the cell of the intestinal epithelium the molecule of the glucoside of digitalis constitutes no stimulus while it does constitute one for the heart muscle. Just as little can a morphine molecule effect an influence on the cell of the bone marrow. In the sense of a general external reaction these bodies are indeed stimulations, but the above cell species, by their very constitution, have no possibility of reacting to this stimulus in a manner typical of them. Their "immanent" specificity has no effective relation to an inadequate stimulation. Such a behavior has been known for a long time in the doctrine of immunity which is explainable by the deficiency of receptors. Accordingly a cell responds upon adequate stimulation only, and then in a specific manner. The law of specific energy of the sense organs has an analogue in the specific irritability of each single cell organism.

Physiologically the cell experiences stimulations only from its own healthy macroorganism, and these are always adequate since they represent on their side functions of personal identical cells or cell groups and therefore arise from the identical general constitution. A renal cell reacts with its specific function, diuresis, only in response to an adequate stimulus. If it were possible to transmit to it a stimulus which would, for example, contract the trapezius muscle, no diuresis could be expected. It would not be adapted to the renal cell and its specific activity. The adequacy involves both a qualitative and a quantitative moment; accordingly there exists adequate physiological and unphysiological stimulation. To this group belongs the electrical stimulation which can produce a specific reaction in the renal cell as well as in the muscle cell, but does not occur as a purely electrical stimulus in the physiological working of the body. The electrical stimulus must by no means be identified with the mere processes of conduction in nerves. Chemical and physical processes of different nature play a rôle not as yet sufficiently investigated, in physiological stimulation.

The classification of possible stimulations may be attempted thus:

A. *Physiological stimuli may be:*
- (*a*) endogenous, i.e., they take their origin in personally identical cells.
- (*b*) exogenous, i.e., acting only upon cells that are receptively adequate in a special manner, such as resorption cells of the digestive canal, or of the lungs, and sensory cells.
- (*c*) always adequate, i.e., they are both qualitatively and quantitatively adjusted specifically to the constitution of the cell that receives the stimulus. This is based upon a common coordinating relation of both factors, namely, the stimulus and the receptive cell.

B. *Unphysiological stimuli may be:*
- (*a*) endogenous: under pathological conditions cells may be formed, the products of which represent in their diseased and changed original substratum a conditional deviation from the personal normal state (toxins of malignant tumors, etc.).
- (*b*) exogenous: of not personally identical origin.
- (*c*) adequate: inasmuch as their nature is of such a character that the living substance can react upon them (thermic, chemical, electrical stimulations). Here the cell reacts by virtue of its innate specificity.
- (*d*) inadequate: the stimulation in question does not represent any stimulus for the cell. There does not exist any chemical or other relation between the stimulus and the receiving cell.

From this survey it is evident that the purpose of every therapy must be the preservation and increment of the healthy function which is most surely achieved when medicaments are used so that the qualities of the physiological stimulus are preserved. At all events, the quality of stimulus designated under B (*d*) must be avoided.

All unphysiological stimuli have the common quality that they are more or less easily exhausted. Eventually habituation to the stimulus sets in which necessitates a continual increase of the stimulus. In the case of employment of some medicaments, even toxic substances in the long run lose their poisonous qualities. The latter may be called only a function of the quantity or of the quantitative intensity of the stimulation; the destructive effect of certain bodies upon the living substance always depends upon a certain minimum. Physiological stimulations, on the contrary, do not lose their effectiveness by the duration of their influence, but only through a general senility of the cells. If physiological stimuli grow ineffective, it means the normal death by age of the organism.

*Read at the annual meeting of the American Therapeutic Society, Washington, D. C., June 3 and 4, 1921.

The sphere of lastingly effective interferences, however, is restricted in therapy by the fact that exogenous physiological stimuli presuppose a specifically adapted cell system for the evolution of their effects. The sharply defined functional relation—digitalis, heart muscle; morphine, brain ganglion cell—is not met with in many cases. Often we are dealing with "polytropic" remedies, as in the case of many alkaloids (atropine, etc.). This "regional breadth" of effectiveness, in the special cases often undesirable, is characterized as a secondary effect, which, however, makes the success of the therapeutic effect questionable.

Under this viewpoint a certain therapeutic school which has only lately attracted attention gains in importance. Through the work of Weichhardt and his collaborators the conception of protoplasmic activation created by this investigator was given at least an empirical importance. The meaning of this expression is to be found in the increased power for work of the living cell due to certain therapeutic influences. General increase of the functions of active organic cells at first resulted from the direct introduction of albumin and albuminous disintegration products into the blood stream with exclusion of the intestinal canal. Weichhardt and Schittenhelm began with investigating the immediate effect of such albumin upon the blood picture, metabolism, and especially the thermic centers. The method then became more generally accessible through the investigations of Rudolf Schmidt and his disciples. They used milk injected in doses of 5 to 10 c.c., as their therapeutic agents. The general effects in this procedure were the same as with the injections of muscle "juice" applied by Weichhardt. An increased temperature and neutrophile leucocytosis constitute the general effect. This method was very soon used in therapy. (Grote, proteintherapy in *Zeitschrift für ärztliche Fortbildung*, 1919, N. 24, where the literature may be found.)

Certain observations upon which, however, we shall not enter, favor the idea that the therapeutically working principle of protein body therapy is to be found in albuminous disintegration products formed by proteolysis in the tissues caused by the proteins that are injected. We are dealing here with amino acids and similar bodies. But these—and that is of fundamental importance—are not essentially different from the disintegration products normally found in the body. Through this method a possibility seems to be given to inject stimuli into the body-cell that are adequate to it. These stimuli, although provoked exogenously, nevertheless work in exactly the same manner as stimuli that have arisen within the body itself.

Already these experiences have been applied to the known immune therapeutic successes with specific sera, and it might be discussed whether or not the effect of tuberculin might not in the last analysis be due to the action of a mere nonspecific protein disintegration product. R. Schmidt obtained from milk injections the same focal reactions as with original tuberculin. Bingel in Brunswick (Monograph, publ. by F. C. W. Vogel, Leipzig, 1918) treated diphtheria with horse serum free from immune bodies; his successes are as surprising as satisfactory. Typhoid fever has been treated in a similar manner successfully by Saxl and Grote. Especially satisfactory were the successes with male and female gonorrhea and its complications. (R. Müller and Weiss). The well-known undeniable good influence of blood injections on anemias of all kinds very likely is due to the same principle.

The important point in this matter seems to be the fact that in reality in this therapy we exert only a physiological stimulation. The body is in no way offered an agent with which the cell cannot accomplish anything. Albuminous disintegration products constantly circulate in the body and their temporary increase is the medium of stimulation which causes the cell to increase its most proper vital functions. This therapy represents an exogenous adequate stimulation which the body itself through fermentative action changes into an endogenous adequate stimulus, bestowing upon it thereby, according to our division, the character of a physiological stimulation.

With this insight there seems to be established the principle according to which all future medicinal and physical therapy will have to work, namely, the *changing of an exogenous stimulation which is accessible to the ferments of the body and which consequently must be adequate—into an endogenous adequate stimulation for the individual cell.*

A more accurate analysis of some hitherto called specific interferences (e.g. serum therapy of carcinoma by Abderhalden, etc.) will very probably show that the same principle is at the bottom. At any rate, the so-called "immune bodies," known hitherto, are not identical with the substances effective in protein body therapy. They may cooperate, but their rôle is only a secondary one, since it appears possible to increase them, or at least to activate them by the physiological stimuli.

It will be the task of future investigation to test the individual disintegration products as to their effectiveness in increasing cell work or cell resistance. Even now it seems certain that not all bodies formed in the fermentative parenteral splitting process are of equal value as to their effect upon the cells.

In the foregoing deduction I have considered also the physical actions. This was done because in physical influences (heat, cold, electricity, Röntgen rays, etc.) similar fermentative splitting processes of protein (protein disintegration) can be presupposed as parenterally originated in the body. But the details are totally unknown as yet. It has been possible, however, to demonstrate such processes in the case of extensive burns.

But this will not put an end to the specific immune body therapy. It means rather a clearer comprehension of its possibilities and purposes. The specific antitoxin, *e.g.* of diphtheria serum, fully retains the significance which is given by its specific binding to the bacterium. But there is the possibility of an essentially increased effectiveness as soon as we shall know the means by which we may assist the living cell of the organism in the functions injured by the infection. That the diphtheria antitoxin itself cannot do. It is specifically adjusted to the bacterium (Klebs-Löffler bacillus). The bacterium, however, is not the essence of the infectious disease. The essence is rather found in the lowered function of the cells in the body.

Therapy directed by these viewpoints, *i.e.* the highest possible conservation of physiological stimuli for the purpose of greatest possible preservation and strengthening of physiological function, will be in the best sense a therapy that can be termed etiological.

SOME OBSERVATIONS ON THERAPEUTIC NIHILISM.*

By F. M. POTTENGER, A.M., M.D., LL.D., F.A.C.P.,
MONROVIA, CALIF.

DURING the past thirty years a revolution has been going on within the ranks of medicine. Coincident with the development of laboratory methods and the discovery of the causes of many diseases prevention assumed the place of first importance while the cure of disease and the relief of the patient's symptoms took a secondary place. With this relegation of the practice of medicine to a place of secondary importance has come a change in the relationship between physician and patient. The old family physician with his medicine case full of pills and his heart full of interest in the patient and sympathy for him in his illness has been almost pushed off of the stage by the man whose chief interest lies in the study of diseases as they appear through the microscope, and in the test tube, and whose thought of the patient afflicted has necessarily appeared to be minimized.

Both the profession and the public have recognized and deplored this change with its inevitable result of separation of interests. The sick man demands more than our scientific medicine is giving him. He requires more than a knowledge of disease and disease processes can furnish. Nor is his illness confined to his material body alone. His condition as a thinking, willing, hoping being is also disturbed. One of medicine's great mistakes has been its failure to recognize that there are two factors to be considered, the patient and the disease; and to give to each the consideration which it deserves. It has pursued its studies and its practice with a lack of comprehension of the nervous and psychic sides of the individual, and a failure to understand his reactions toward disease that seems inexplicable.

The older medicine without the knowledge of the causes of disease and of pathological changes in the tissues caused by them, which we possess today, failed to satisfy the investigating mind of medical men, but it gave much comfort and satisfaction to the patient, because it made him the center of interest. Modern medicine with its development of the various laboratory branches and specialties has taken upon itself a far more scientific aspect than the medicine of previous times, which has been a great source of satisfaction to the profession; but can we claim that it is appreciated by the layman to the extent that our belief in its superiority warrants? If not, why not? The answer is very complex, but I desire to point out a few facts that I believe are fundamental to its understanding.

The age through which we are now passing has been dominated by bacteriology and pathological anatomy. It has been an age in which the study of material factors has received greater attention than nervous and psychic. Pathologists, too often, have been out of harmony with the efforts to treat the sick, and too often, with an air of superior knowledge rather than an air of helpful suggestion, have shown at the post-mortem table the errors of the clinician's diagnosis. They, too, with dogmatic assertion have announced that therapy can not change the pathology of disease. Those who have been best informed in pathology have often been most pessimistic as to the accomplishments of clinical medicine in both diagnosis and therapy. Unfortunately this pessimism on the part of the more scientifically trained toward the practical application of discovered facts to the relief of symptoms and cure of disease has led to the study of the problems of each branch of laboratory medicine as a specialty with insufficient thought to its application to the practice of medicine. It has also made the path of those who practise medicine unnecessarily difficult.

Aside from this group of ultra scientific men there have been those who have been obliged to minister to the sick and help those who are ill to overcome their disease. They have not always measured up to the height of scientific standards in their work. They have had a hard time to square their accomplishments with their own ideals; but they deserve honor to the extent to which they have added to the sum of medical knowledge and succeeded in applying it to the relief of those who are ill. Some practitioners of medicine have assumed a disinterested attitude toward the laboratory side of medicine which is comparable to that of the many laboratory workers toward medical practice. This is illustrated by the following incident. A physician was doing post-graduate work in Vienna. Some of his colleagues were telling of the wonderful opportunities for study under Prof. Weichselbaum and his assistants in the Pathologic Institute and invited him to go with them. He replied "Weichselbaum never cured anybody." This practitioner, who only wanted that which would aid or cure his patient, and the pathologist, who laughs at the errors in diagnosis and ridicules the attempts at curing disease, represent the extremes in medicine. The one's opinion reflects the pessimism which comes from an appreciation of the paucity of our real knowledge and a lack of sympathy for the problems of administering to the needs of the sick; the other shows a failure to recognize the importance of a study which does not directly aid one in his desire to meet the demands which are made upon him to do something to relieve his patients.

The main error on the part of the pathologist is that he assumes too much for his branch. He has assumed a place of much greater relative importance for pathological anatomy than time will accord it, after the correlated branches of medicine have been thoroughly developed. No one ever will be accused of knowing too much pathological anatomy, but the error is in measuring its importance in relation to medicine as a whole. The error on the part of the practioneer is that he recognizes the problems of the practice of medicine but fails to see that the knowledge derived from the study of these laboratory branches is essential to the unfolding of the science

*Read before the twenty-second annual meeting of the American Therapeutic Society, Washington, D. C., June 3 and 4, 1921. (See page 475.)

of medicine, and that the greater medicine can come only through correlating the knowledge derived from study in all of its branches.

Physiology is one of the most important studies in medicine. Normal physiology contrasted with pathological physiology, gives our disease pictures and furnishes data upon which to make a diagnosis and establish a therapy. Further, physiological action is subject to change through therapy. Even pathological anatomical changes in tissues are sometimes brought about by altering physiological function and are relieved by correcting it. The study of pathological anatomy, although not intentionally nor necessarily, has fostered medical pessimism and the spirit of therapeutic nihilism; the development of pathological physiology, on the other hand, will bring a clearer conception of the working of the human machine in health and disease and will add intelligence and optimism to diagnosis and therapy.

The development of diagnosis and therapeutics will be greatly aided, if our profession can only obtain a broader grasp of what medicine is. Medicine is a comprehensive study of the causes of disease; the prevention of disease; the effects of disease upon the body tissues; the manner in which functions of the body are disturbed by its presence; the nervous, endocrine and psychic imbalance which is brought about by it; and measures for the cure of the patient or the relief of attending symptoms.

Each branch, whether it be pathological anatomy, bacteriology, biochemistry, physiology, pathological physiology, psychopathology, or any other, is only a part of medicine. One branch may be of greater importance than others in the minds of the profession at one time and in the minds of some members all of the time; but one must never lose sight of the fact that they are one and all only of interest to medicine as they can furnish information which helps to prevent or cure disease, relieve symptoms, or alleviate suffering.

Therapy will be a legitimate and necessary branch of medicine as long as illness exists. No pessimism can destroy its usefulness and no nihilistic attitude can remove it necessity. If therapy is a necessity, then it is the duty of medicine to develop those phases of study which will make it more accurate and more successful.

No one can read medicine without recognizing the force of the struggle for better therapeutic measures. This struggle, however, has not been guided by a clear conception. Much of the effort in the past has been confined to the discovery of plants with medicinal virtues and chemicals which would in some way relieve symptoms. There has been too much of a tendency to confine ourselves to drugs and surgery to the exclusion of physical and psychical measures.

This grasp of therapy has been wrong. While theoretically our profession stands ready to employ any measure that will aid in the cure or relief of disease, in practice we have been extremely narrow in our attitude toward remedial measures. Probably the majority of graduates from medical schools in the past have left college with the idea too strongly in their minds that disease was to be cured, if at all, by drugs or surgery. The fact is that they have graduated without a true conception of what the practice of medicine means.

It is no wonder that medicine has found itself so vulnerable to the attack of isms and cults which have arisen during recent times; for in its own ranks it has many who scoff at therapeutic attempts. The purely scientific worker, often possessed of the best brains of the profession, rarely interests himself in therapy and is too often content with the statement that drugs influence disease processes but little, if any; and the surgeon, carried away by his brilliant advances in his field and not yet fully appreciating the shortcomings of his therapeutic attempts, is too much of the opinion, "surgery or nothing." On the other hand, there are many practitioners who from their intimate contact with the sick, make an earnest effort to find methods for relieving symptoms and cutting short the period of illness. The more eminent the man the less he depends upon drugs and the more he prescribes proper care and regulation of the patient's life. The physician with less knowledge and reputation, however, is apt to depend mostly upon drugs for his results.

Medical teaching fails utterly in preparing men for meeting the therapeutic demands made upon them in practice. The graduate in medicine is imbued not so much with trying to help the patient as with trying to understand his pathology, bacteriology, and pathological chemistry. The patient on the other hand desires relief from his symptoms, and has no interest in the recognized scientific lines of study unless they give him relief.

While some disease processes have anatomical changes standing as causative, others have them only as a result. All, however, show physiological change resulting in disturbances in normal function. It is the duty of physicians then, to study thoroughly normal and pathological physiology, to learn what governs the normal working of the human organism, and to recognize the manner in which disease alters this. This leads to a thorough study of the nervous, endocrine, and psychic controls of the body with the application of remedies and measures which will preserve or restore their balance when disturbed.

In a former paper, in discussing this point, I called attention to the fact that normal physiological action is under the control of the nervous and endocrine systems and that during disease these systems are disturbed by stimuli which are of either physical or psychic origin. It seems to me that this covers comprehensively the control of body action in health and in disease.

It is the duty of medicine to comprehend these controls fully and also to learn the things which will restore them to normal when altered. Drug therapy is based on the action of substances, upon nerve and chemical control. To the extent that we learn the physiological action of drugs shall we be able to use them with intelligence. One would think from the teachings of materia medica that the principal way of influencing disease is by drugs, but in practice such is not the case. Any measure that may be employed to remove or directly combat the cause of disease or to counteract the pathological action of any organ or tissue may be utilized in the treatment of disease; so may any measure that will increase the normal stability of the nervous and endocrine systems and improve the physical and

psychic condition of the patient so that he will better withstand the disease.

The treatment of the sick then is accomplished in three principal ways: one by attempting to remove that which is causing the disease, another by restoring disturbed function, and a third by attempting to stabilize the nervous and psychic equilibrium and aid the organism in making its own fight to overcome disease. The first has been considered the most scientific during recent years, but because of the limited headway that it has made, it has caused great discouragement to practitioners of medicine. The other methods, while not having as yet fully gained the recognition of scientific men, have been gradually gaining in general favor. Practitioners are beginning to see that anything which will aid the sick is worthy of our profession, and that it is necessary to continue aiding the patient in whatever way we can even if specific remedies cannot be had and the cause of the disease cannot be surgically removed.

As we turn to this rational view of medicine, it brings with it a demand for a closer study of the patient than we have heretofore given him, and a better understanding of his normal and pathological reactions. At the same time it offers a hope for the displacement of pessimism and nihilism in therapeutics and the establishment of a basis upon which medicine can render a more efficient service.

THE FUTURE OF THERAPEUTICS.*

By REYNOLD WEBB WILCOX, M.D., D.C.L., F.A.C.P.,
NEW YORK.

TWENTY-ONE years ago last month this Society was organized under the presidency of Professor Horatio C. Wood in this city. According to the critics this Society was entirely superfluous because, in those days of the full flower of therapeutic nihilism, therapeutics was as non-existent as is disease in the concept of the blind devotees of a contemporaneous cult. But the founders of this organization, men of deeds and with prophetic vision, realized that the theories of the nihilists were incompatible with the proper fulfillment of the duties and obligations of conscientious practitioners of the art of healing. They realized that a thorough knowledge of pathology was essential and that diagnosis was important, and equally well that the period which should elapse before the necropsy should confirm or modify the diagnosis ought not to be one of watchful waiting if the duty of the physician to the patient was to be properly appreciated and fulfilled. In other words, an idle observation of the combat of the human organism against infection or the progress of degenerations of important organs or the impairment of functions, no matter how interesting these might be, was not the sum total of the professional activities of the attendant. Indeed, this inactivity, considered in the light of results, differed little from the beating of tom-toms of the aborigines or its modern successors, the reading of congeries of words, meaningless, irrelevant, immaterial, and incompetent in the presence of a real tragedy.

Slowly but surely the profession has come to realize that he who proclaims that there is no treatment of disease simply asserts that that particular individual knows no treatment and the term therapeutic nihilist has become coterminous with that of therapeutic ignoramus. Further the contemplation of the end results of disease and the study of the havoc wrought by morbid processes, as carried out in the dead house, beget a feeling of pessimism as to the effectiveness of methods and means employed to combat disease. And as it began to be realized that the ruins of the fireworks on the morning of the fifth of July gave little ground for an estimate of the oratory, the enthusiasm, and the more deeply grounding of patriotic sentiments and founding of nobler aspirations of the preceding day, so the despair of the pathologist became out of place in the clinician who knew his resources, as well as their limitations, in alleviating suffering and in the cure of diseases. Hence the cheerfulness of the expert and the hopefulness of the conscientious practitioner made for a more favorable prognosis not only for the patient but as well for scientific knowledge. What has been said applies not only to the domain of internal medicine, for it is here that a real cure, a *restitutio in integrum*, is the goal more frequently reached, but to surgery also, although that often is a process of subtraction, and to the limited specialties. So this Society, early in its history, has enrolled in its membership representatives of all departments of professional activity to the advancement not only of group therapeutics but also of therapeutics in its broadest meaning which has been the outstanding purpose of this organization. If we had accomplished nothing more than this the *raison d'être* of our Society would have been amply justified by the results.

But our achievements have not been limited to the general acceptance of the fact that pathology is not the whole nor even the major jart of medicine; we have demonstrated that pharmacology is not all of therapeutics nor even a respectable moiety of the healing art. This Society pointed out in 1903 (Transactions, Vol. II, p. 26) that a necessary basis for the highest development of the art of therapeutics should be: (1) A practical acquaintance with various remedial physical measures and remedies, not less physiological, and methods of preparing the latter. This should be acquired during the early and mnemonic period of the student's career (recitation and demonstration). (2) Actual knowledge of the action of agencies and remedies acquired by personal experimentation and demonstration under the teacher's eye (laboratory demonstration). (3) Application of these agencies and remedies, the actuality of their effects for good or evil having been fixed in the student's mind, in the treatment of diseases and symptoms, under proper supervision (lecture and clinical demonstration). (4) The actual direction for the exhibition, in strict pharmacopœial nomenclature, of remedies and the scientific use of physical agencies must be so thoroughly comprehended by the student that he can not only intelligently apply them, but give valid reason for his treatment (clinical practice and conferences). That the schools have not been alive to the importance of this basis for education, thus categorically expressed, is the fact that a *questionnaire* sent out by one of the most important, if not the most im-

*Read before the twenty-second annual meeting of the American Therapeutic Society, Washington, D. C., June 3 and 4, 1921 (See page 477.)

portant, of the medical schools, to graduates of more than ten years' standing, elicited the information that more than three-quarters of those who reported attributed their failure to obtain their hoped-for success in practice to the imperfect teaching of therapeutics in the school from which they had obtained their degree. That this is not either a local, or an unusual condition is evident from reading a forcible paper which was presented at our last meeting in Philadelphia by Spencer L. Dawes. Further evidence, if such evidence were wanting, is contained in the assertion of the dean of a medical school which for many years has enjoyed the traditions of a faculty of national reputation and a graduate body of successful practitioners of which a respectable number have been of great reputation for ability and professional skill, and remarkable for their loyalty to their *Alma Mater*. This school has recently been reorganized along the lines of emphasis upon the laboratory and preparation for the student's life work largely founded upon generalities of treatment without special emphasis being placed upon an actual knowledge of the materials used in the treatment of disease and their application to the concrete problem under consideration. This dean in explaining the failure of this new system makes the naïve assertion that success in the practice of the healing art depends largely upon the personality of the practioneer, apparently not realizing that the primary and proper function of the medical school is to educate competent physicians and surgeons. In attempting to develop investigators he fails to realize that some potentially successful practitioners may fail to attain their greatest usefulness because of his system. It would seem that in the classification of medical schools, not only the form of instruction should be determined, but the character of the instruction and the amount of it considered in its proper perspective, that is its bearings upon the equipment of the profession of the future which must take up the work which is new being done by the successful practitioner of the present.

Another set of critics predicted the ownership of this Society, or at least its control, by some enterprising group of manufacturers of materia medica products basing their prophecy upon the history of similar organizations (societies or sections). Article X, Section 3 of the By Laws reads as follows: "No paper, report, abstract, or other communication either written or verbal, which, directly or indirectly, commends or advertises any secret, patented, or trade-marked products, or method of treatment, shall be presented to, or received by the Society; nor shall any discussion upon such products, or methods, be permitted: Provided that nothing in this section shall be construed as presenting adverse action upon such subjects." This section, rigidly enforced and conscientiously lived up to in the letter and the spirit, has resulted in the disappointment of the prophets of disaster.

As to the Pharmacopœia, this Society has always realized its importance and earnestly advocated that the profession become better acquainted with its resources and employ its open, standardized, and eligible preparations. Many members have taken an active part in the decennial revisions which have been made during the life time of this Society.

The importance of the dissemination of accurate and impartial knowledge of the unofficial remedies was early a subject for discussion and action by this Society, and this finally took concrete form in the National Bureau of Medicines and Foods as was originated and proposed by Francis E. Stewart (Transactions, 1903, Vol. I, p. 62). Later the plan, although not in its entirety, was put into practical operation as the now-known Council on Pharmacy and Chemistry, which has been of great benefit, through the publication of the results of its activities, not necessarily constructive, to all workers in the domain of medicine and surgery (Transactions, 1908, Vol. IV, p. 69).

In constructive work to every department of the science of therapeutics this Society has made fruitful and substantial contributions. Every volume of the Transactions has recorded marked progress in the underlying sciences which has markedly improved the practice of therapeutics in its broadest sense. The value of therapeutics is now unquestioned, and the accumulated knowledge, as shown by the work of this Society, has placed the entire profession under obligation to it. With this record of unparalleled success we may well venture to prophesy and with better hope of success than our critics enjoyed two decades ago.

To predict what shall be the future of therapeutics we must bear in mind the abandonment of the methods of investigation which obtained twenty years ago which was the determination of what lesions produced given symptoms and signs and from their consideration deduce the method and form of treatment. Morbid anatomy was then largely the basis of therapeutic endeavor. To-day we strive to ascertain what disturbances of function produce symptoms and to determine during life how the body functions; in other words, anatomical considerations have largely been replaced by biological conceptions and for their study laboratory methods have become of increasing importance, and in so far as they explain the mechanism of variations from the normal they furnish the premises upon which we may base conclusions which may be helpful for diagnosis and prognosis, and especially as affording valuable indications for therapeutics in the broadest sense.

We require as thorough, accurate, and conclusive laboratory investigations of the effects of climate, the various phenomena of the atmosphere as regards temperature, moisture, and other qualities as they affect human life, of physical agencies, as electricity in its various forms of application, of the Roentgen and other rays, including radium emanations, of the effects of exercise and of diet, of massage, including the more limited in form but violent in quality now in some vogue, of the functions of the endocrine bodies, and of psychological operations as influencing somatic processes now chiefly employed by individuals of abnormal mentality—as those investigations which have been carried out for decades in the domain of pharmacology.

Fundamental to the productiveness of these investigations must be a great improvement in the equipment of the workers and a standardization of their technique especially in the field of biochemistry. For instance, the same specmien of blood should not be reported as Wassermann negative by

one, one plus by a second, and three plus by a third observer. The same variations as to blood sugar, purin bodies, or creatinin are by no means unusual. Patience, thorough technical training, and judicial temperament combined, in the laboratory will make for more confidence in their findings. The conclusions to be drawn must not be entirely left to the laboratory worker, for some are known to possess, and sometimes exhibit, a very vivid scientific imagination. The final conclusion must be arrived at by one who not only knows the methods but as well their limitations, and by correlating these findings with those based upon observations in broader methods of investigation and chastened by practical experience, a more sound decision can be reached and one of greater value in determination of therapeutic measures.

Even in pharmacology the field of usefulness of laboratory investigation may be greatly enlarged. In endocrinology much may be placed upon a firmer foundation. For substances derived from the indigenous vegetable kingdom of extensive use by a well known and earnest group of practitioners, many of important action should be the subject of intensive study, in order that their employment may be more intelligent than is possible from purely empirical tradition. It is needless to remark that the great complexities of chemical composition peculiar to all substances of vegetable origin add to the difficulties in reaching accurate conclusions. *Questionnaires* have shown that cactus is in frequent use in the treatment of cardiac and circulatory disorders comparing favorably in extent even with digitalis. Yet scepticism as to its value is frequently expressed, based apparently upon the results of laboratory work by an English observer. As his results were so out of harmony with the practice of excellent clinicians, the most important botanist in this country reported that the material used was an interesting plant in no way related to the substance supposed to have been used. Later a laboratory worker in this country undertook another investigation and reported the substance inert. As the conditions under which this investigation was undertaken were peculiar, it would be charitable to suppose that the material employed was not an active one, due to faulty collection and selection or pharmaceutical preparation. Yet any one who knows how to employ instruments of precision can demonstrate that any of the active preparations of this plant possess the peculiar properties of increasing the frequency and force of the cardiac contractures. Such laboratory investigations as these only reflect upon the accuracy, honesty, and general credit of the pharmacologist, and detract from his reliability.

The investigator, assuming that he is competent, thorough, and honest, is useful, even indispensable, in blazing new paths in the domain of knowledge which may be made of practical use. He is equally important in that he may place the methods and material, which have been employed empirically for decades, upon a sure and broad basis.

But the results of laboratory investigation must not be accepted without question; their value must be established by the conclusions based upon actual employment in the practical work in the art of medicine; the clinician pronounces the verdict and upon this the scientific value of laboratory conclusions must stand or fall. From clinical observation we look to the laboratory for explanation, modification of judgment or rejection upon experimental data, but we come back to clinical observation, and this is the basis of therapeutic advance.

In fine the future of therapeutics in its broader sense rests primarily upon the diminishing importance of morbid anatomy with the increasing study of pathological physiology, for pathology is merely physiology which has become abnormal; upon the deductions from intensive work in biological chemistry of more accurate technique, and upon a more searching analysis of clinical results; and upon the intelligent practice of the science of therapeutics may be based the art of therapeutics, which is the aim of all practitioners sincerely devoted to the alleviation of suffering and the cure of disease.

The wonderful advances of the last two decades of the life of this Society in the treatment of infectious diseases, disorders of metabolism, and degeneration in various physical systems, the production of immunity either special or general, and the clarifying of scientific knowledge are an earnest of the therapeutics of the future the basis of which must be established in the carrying out of the essential methods herein set forth. From our past record we can assuredly predict that in the placing of therapeutics, in its broadest sense, upon competent instruction of the student, upon accurate investigation in laboratory, and upon logical analysis of the results of clinical experience this Society will continue to be productive in the dissemination of knowledge of the science and contribute very largely to the practice of the art of therapeutics.

WHAT CAN THE ASSOCIATION OF CARDIAC CLINICS DO?*

By ROBERT H. HALSEY, M.D.,

NEW YORK.

Recently this question has been put by so many persons and organizations who are interested, that it may add to the clarity and value of the discussion if a statement is made of a few of the ways in which profitable results may be gained. It will be evident at once that cooperation by all the components is necessary for the fullest results and, with such union, there will be valuable returns to patient, doctors, and hospitals.

The Association of Cardiac Clinics depends upon the component cardiac clinics, therefore a review of the possibilities of such units will make clear the opportunities.

For the best care of any special group of patients; and this is particularly true of patients with heart disease, because of the very technical difficulties in such diagnosis, it is necessary to have a sufficient number of physicians, who are deeply interested and well enough trained to carry on an intensive study of wide range and inherent difficulty. The clinic should have all the facilities of, and the physicians should be an integral part of the staff, of the gen-

* A résumé of remarks made at the first meeting of the Association of Cardiac Clinics at Boston, Mass., May 20, 1921.

eral medical service with its out-patient ward and social service organization.

In the out-patient service, the patients should be studied first and segregated, just as dermatological or orthopedic cases are, from every other service. They should be examined by all the usual recognized means of physical diagnosis and, when necessary, by means of the technical instruments, fluoroscope or electrocardiograph. The reference to the collaborating departments of eye, dental, nose and throat, *x*-ray, and laboratories equipped to examine chemically, bacteriologically, and serologically when necessary, should be a routine. There may be patients who will require a stay in the ward for a better examination, a course of drug treatment, or some therapeutic procedure such as tonsillectomies. No cardiac clinic properly run will long carry on without requiring a sympathetic, tactful, executive social service worker and her full time. Many patients may be kept out of the hospital and at home by the skilled and well advised visiting nurse. She must, and can, be the intelligent go-between of doctor and patient when their actual contact is not required.

The functions, therefore, of a clinic may be grouped under the following:

1. To diagnose the presence or absence of impaired cardiac function. It may act as consulting physician to (*a*) public schools, and (*b*) other organized charity groups.

2. To classify patients attending clinic by some practical method which will be expressive and facilitate the care of the patient by physician, social service department, hospital, and convalescent home.

3. To educate and advise the patient and family of the patient of the type of handicap and the various means available for increasing the efficiency or earning power of the individual.

4. To follow-up, to encourage, to stimulate confidence, and to insure the carrying out of treatment—preventive, operative, or remediable, drug or serological, recreational or therapeutic graded exercises.

5. To advise the need of and send to a suitable country home for special outdoor constructive treatment.

6. To guide to proper vocations the school graduates and place, or replace, in suitable occupations to continue or increase the earning capacity of the handicapped adult.

7. To collect in orderly records accurate data from a study of which advances in the treatment of heart disease may be suggested.

Comprehending the above lines of service which readily evolve from an up-to-date application of our present knowledge, the association of several such units will at once facilitate and coordinate the administrative work by

1. Coordinating clinic standards and requiring the equipment as described above.

2. Promoting constructive discussion and use of a classification such as that adopted in 1921 by the New York Association of Cardiac Clinics.

The classification of patients attending a cardiac clinic.

Class I—Patients with organic heart disease who are able to carry on their habitual physical activity.

Class II—Patients with organic heart disease who are able to carry on diminished physical activity: (*a*) Slightly decreased. (*b*) Greatly decreased.

Class III—Patients with organic heart disease who are unable to carry on any physical activity.

Class IV—Patients with possible heart disease. Patients who have abnormal physical signs in the heart, but in whom the general picture, or the character of the physical signs leads us to believe that they do not originate from cardiac disease.

Class V—Patients with potential heart disease. Patients who do not have any suggestion of cardiac disease, but who are suffering from an infectious condition which may be accompanied by such disease; *e.g.* rheumatic fever, tonsillitis, chorea, syphilis, etc.

3. Increasing the efficiency and service of the social service by districting the city.

4. Promulgating and diffusing knowledge of advances in the diagnosis, treatment and social service care of patients with heart disease.

5. Stimulating the convalescent homes to properly equip themselves to care for cardiacs. Selecting proper cases for such homes and advising the homes as to what the individual patients with heart disease may do to accelerate restoration of function. Encourage homes to preserve the continuity of supervision by reporting back to clinics from which patients come, the behavior and results of stay at home, by some such filing card device as adopted by the New York Association of Cardiac Clinics.

6. Organizing and encouraging a bureau to gather all available knowledge concerning vocation and employment, and maintain it for consultation by clinics, public health organizations, child

labor committees, employers of labor, or other interested persons.

7. Organizing cooperation of clinics in the collection of data concerning heart disease for a wider study than is possible in any one hospital or by any one man.

In the achievement of some of the results enumerated, the Cardiac Clinics of New York City have made a very definite step forward both individually and through the organization of the Association of Cardiac Clinics which is now represented in the Associated Out-Patient Clinics of the City of New York.

THE ROLE OF RADIUM IN SURGERY.

By MARC V. ABRAMS, M.D.,

BROOKLYN, N. Y.

THE discovery of the activity of radium, and its therapeutic application in medicine and surgery, was as important an event as was the discovery of the roentgen ray.

The medical profession, like any other scientific body, is ever eager to hail new discoveries with extreme enthusiasm. Expecting too much from a therapeutic novelty, and not obtaining the desired results, it is dismissed with undeserved condemnation. This has been true of many valuable medical discoveries, and is applicable in the case of radium. On the strength of some exaggerated statements radium has been hailed as the long-expected cure of cancer, and the notion of radioactivity has inflamed some minds to expect results far beyond present possibilities.

When the Curies had collected and insolated radium, they found that the new metal was endowed with astonishing properties. There issued from it continuously radiations (which may be compared with electrified corpuscles) extraordinarily minute, and with a velocity almost equal to that of light. The radiating property of the element would take three thousand years to exhaust itself. There are three distinctly different types of vibrations or emanations, characterized by different effects upon tissue and matter. These are known as the alpha, beta, and gamma rays.

The alpha rays constitute ninety per cent. of the radiations of the metal. These, because of their low efficiency, have little value in radium therapy. The beta rays comprise nine per cent. of the radiations. These also possess little penetrating power and are utilized in the treatment of superficial lesions where they can be directly applied. The gamma rays, which represent only one per cent. of the radiations, are in their character analogous to the Roentgen ray but of greater intensity. They are capable of penetrating iron and stone to a considerable depth, and are of therapeutic value. The gamma is neither a burning nor an irritating ray. It acts directly on the nuclei of malignant tissue cells. Since these are embryonal in nature, the malignant tissue is acted upon and destroyed before the normal tissue cells are appreciably affected.

Radium as now used is generally employed with filters or screens of gold, silver, lead, brass, or aluminum. Any of these metals, one millimeter in thickness, is capable of filtering the soft alpha and beta rays which produce the cutaneous burns. In the passage of the primary rays through these screens, secondary ones are produced from the metals. These secondary rays are stopped in their action by filtering with sheet rubber.

Emanation is another property of radium. It results from the radioactivity. The emanation may be passed off into the atmosphere or into water.

Methods.—The methods of applying radium are varied. It was first employed in little glass tubes and applied to the surface of the diseased tissue. Later these tubes were buried in tumor masses. After that, radium was incorporated in a varnish, and plaques were made for surface application. At present the element is standardized in regulated quantities of milligrams which are placed in non-corrosive needles or metal tubes and the gaseous emanation is collected in very small glass containers. The needle applicators have a twofold usefulness; they may be used for superficial lesions, or inserted directly into a tumor mass. Filtration or screenage is readily accomplished when a specific quality of the ray is desired. The cross-fire method of applying radium is accomplished by placing two or more tubes on opposite sides of the part to be treated, or by making two or more applications from different directions. Thus it is possible by this means to get a pronounced result upon a tumor without too much effect upon the overlying skin or mucous membrane.

Dosage of Radium.—A milligram hour represents one milligram of radium applied for one hour. An erythema dose represents one thousand milligram hours of radium, delivered to a square inch of skin surface at one inch distance, filtered through the silver wall of the applicator and two millimeters of lead. A lethal dose is three times an erythema dose. The term "distance screening" indicates that some substance such as cork, gauze, or felt has been interposed between the radium and the skin surface overlying the area to be treated. The distance bears a relationship to the amount of radium used and the depth of the lesion beneath the skin surface. For deep-seated lesions, a resisting filter of lead, brass, etc., from one to three millimeters is used and about one millimeter of metal is employed for every thirty milligrams of radium used. The object of this is to permit only such rays to pass through as will act uniformly upon the whole mass of the tissue by penetration. The time element in the application depends upon the quantity employed as well as on the size and depth of the area to be treated. The skin surface will not bear more than three hours continuous application without injury.

Technique.—As is the case with all physical methods of treatment, technique is of utmost importance. The personal equation and the familiarity and acquaintance of the operator with the method play an important rôle in successful application. There is no definite standardized technique but efforts are now being made to formulate the results of various operators in order to develop a universal method for the treatment of particular lesions or conditions.

*Read before the Greater New York Eclectic Society, May 10, 1921, and East New York Medical Society, June, 1921.

Action.—The action of radium is twofold. It first acts on the cell and then on the blood-vessel. Like the Roentgen ray, it is not selective in the sense of destroying or eliminating any particular tissues, but when employed in sufficient quantity, it destroys those of low vitality first. The radium causes a swelling of the cell, followed by a swelling of the nucleus, resulting in a bursting of the entire cell which is absorbed by the blood stream. Its action on the blood-vessels is manifested by a swelling of the tunica intima followed by the production of an obliterating endarteritis in the small vessels. It has been calculated that if a specific dose of radium possesses the power to kill a diseased cell or a new growth cell, it would take five times the same dose to kill a normal adult cell. In small quantities radium stimulates normal tissue; larger amounts produce congestion first and fibrosis later. If exposures are prolonged, and the infiltration insufficient, the action of the rays may become caustic, or the process may result in necrosis and sloughing. With proper exposure there will be an inflammatory reaction which slowly subsides. Fibrous tissue forms, cutting off the blood supply with necrosis if the action is rapid, or atrophy if it is slower.

Therapeusis of Radium.—What the practitioner of medicine is particularly interested in, is the therapeutic efficacy of radium and the permanency of its results. Conditions that have responded most favorably to the applications of radium with or without *x*-ray therapy are: Cancer of the breast, splenomyelogenous and sympathic leucemias, epicomas, Hodgkin's disease, tuberculous adenitis, splenomyelogenous and lymphatic leucemias, epitheliomas, uterine myomas, goiters, nonmalignant uterine hemorrhages, and various cutaneous lesions such as nævi, keloid, and lupus.

Cancer of the Breast.—In treating a primary carcinoma of the breast with or without metastasis, a thorough radiation is indicated before operation, followed by radiation after operation as soon as convalescence permits. Patients in this group have received repeated radium and *x*-ray treatment when a general anesthetic was contraindicated owing to some myocardial change, thoracic, or renal complication. The primary results in all of such cases have been very encouraging. The irradiation decreases the glandular cells and increases the fibrous stroma. It first stops all proliferation, producing fibrosis of the lymphatics. This mechanical choking seems to influence the constitutional resistance of the patient. Patients with recurring carcinoma of the breast with or without metastasis improve under the treatment. Ulceration and sloughing are prevented. Roentgenograms of the chest are taken before treatment in order to determine the depth of the metastasis. If the condition is an operable one and ante-operative radiation is instituted, it renders latent many foci of malignant growth. To quote Dr. William J. Mayo in his presidential address before the Clinical Congress of the American College of Surgeons, where he advocated anteoperative radiation in the following words: "Radiotherapy has justly achieved a reputation in the postoperative treatment of cancer. It would appear however to have its greatest field of usefulness in preparing a malignant area against wound grafting during operation, and its ability at least temporarily to reduce the vitality of the malignant cell. Radiotherapy, whether applied as radium, *x*-ray, or heat, sickens malignant cells beyond the area of destruction. During this period of cell-sickness, their resistance is reduced and operation is most efficient; but operation should not be delayed after radiotherapy, since the period of increased cell vulnerability is short and the connective tissue development which interferes with subsequent operation is rapid. By properly combining radiotherapy and surgery we can increase operability, lower mortality, and increase the percentage of cures. Radiotherapy destroys cells for a certain distance, but cells are sterilized at a greater distance, so that their reproduction is checked and connective tissue is caused to develop, which acts as a barrier to the further extension of the malignant process."

Dr. Schmitz of Chicago states that in malignancies it is advisable to use the combined treatment of radium and Roentgen rays. The former attacks the tumor locally, and the latter acts on the surrounding tissues and organs and regional lymph glands. Surgery removes diseased tissues and organs, but cannot modify their pathological state. Radium and Roentgen rays can modify abnormal cells, but cannot remove them. Therefore it is evident that the combination of the two methods of treatment will increase the efficacy of one or the other. Furthermore he states that in his clinic, if they decided to apply radium and Roentgen rays in malignancy they did so either because surgery could not benefit the patient any more, while the rays gave some hope of palliation, or because the rays would increase the efficacy of surgical treatment. His method of treatment in malignant or potentially malignant disease was as follows: He first applied *x*-ray and radium to weaken the abnormal cells. Then he surgically eradicated the diseaser tissues and surrounding areas. This was followed by final applications of the combined rays to destroy any diseased cells or cell nest that might not have been removed.

Cervical and Uterine Lesions.—Radium has taken an important place in the treatment of cervical and uterine conditions. Excellent results have been obtained in primary cancers of the cervix. Most gynecologists concede that radium is the best palliative measure in inoperable and recurrent cancer. Local disappearance of the disease takes place in some cases, while marked improvement is noticed in a large portion of others. After treatment, the offensive discharge disappears. Where there are broken down masses of cancerous tissue, the deodorizing effect is remarkable. Many of these patients show an irregular temperature from absorption of broken down material, but this generally disappears after the application of radium.

Sarcoma.—Round cell sarcomas respond rapidly to radium therapy. The spindle and giant cell sarcomas respond more favorably than the melanotic type. If the involvement is confined either to the chest or to the abdominal cavity. Radium is applied to the anterior surface, and deep *x*-ray therapy is given through posterior and lateral abdominal and thoracic walls by the cross-fire method.

Hodgkin's Disease.—The treatment of acute and chronic cases of Hodgkin's disease is identical. The

first type is less amenable to treatment on account of its rapid clinical course. The majority of patients are treated for cervical, supraclavicular, axillary, and inguinal involvement with or without splenic enlargement. Roentgenograms are taken of the chest, abdomen, and pelvis to ascertain the amount of involvement of the deep lymphatics. Superficial lymphatic enlargements are mapped out and an erythema dose is delivered to each. If there is splenic enlargement, the organ is radiumized. If the Roentgenograms show involvement of the deeper lmyphatics, deep *x*-ray therapy is applied to the respective areas.

Leucemias.—More radium is given in the cases of acute splenomyelogenous conditions than in the chronic cases, in order to put the patient in a chronic state as rapidly as possible. Satisfactory remissions are produced by the surface application of radium. The results in general are a rapid reduction in the size of the spleen, a fall in the leucocyte count, and improvement in the general condition. During the treatment the blood is examined. If the hemoglobin and red cells decrease, the treatment is discontinued and a long rest given. All patients are supported medicinally during the period of treatment.

Myoma Uteri.—Dr. John G. Clark of Philadelphia states: "As a result of five years' experience in the use of radium, it should be considered as an adjunct of surgery and not its competitor. The fact is that radium has worked very well in certain types of myoma uteri and has rendered much easier the life of patients afflicted with incurable cancer." He further states that menorrhagia is the hallmark of a myoma, regardless of its excess, whereas the tiny spot of intramenstrual bleeding is always a danger signal of cancer never to be considered carelessly. Therefore the criticism that in treating myomata with radium, one may overlook cancer, is not based on clinical facts.

Tuberculous Adenitis.—The simple type of tuberculous adenitis offers the best results. If suppuration be present, curetting or drainage may be necessary. The patient is supported by general hygienic and dietary measures. Hyaline or calcarious adenitis may be an end following radiation.

Goiter.—In the various kinds of goiter, regardless of their etiological cause, certain and distinct changes occur in the thyroid gland, in the blood, and in some of the other organs. Many observers have noticed an almost universal proliferation of the glandular cells, an increase in the connective tissue with certain groups of lymphoid tissue scattered through the connective tissue, and enlargement and multiplication of the blood vessels. The colloidal material is scanty. There is lymphocytosis and decreased polymorphonuclear neutrophiles suggestive of disturbance of the lymph stream. This is further evidenced by the presence of an enlarged thymus gland. Dr. Melchior found from personal experience and from data collected from one hundred and fifty-one papers that an unduly enlarged thymus occurred in about ninety per cent. of exophthalmic goiters. In undertaking to treat this disease, we must consider medicinal treatment, surgery, and ray therapy. As the etiology is unknown, we must attack it symptomatically and with regard to what is known of its pathology. Medical and hygienic treatment have an undoubted place, but should not be persisted in until degenerative changes have taken place in the heart.

Dr. Crile of Cleveland is of the opinion that nonsurgical treatment should always be tried. The results of surgery have not been markedly successful. Dr. DaCosta states that it is the Mayos' custom to radiate for several weeks and then to operate. As noted above he also uses the rays preliminary to operation in order to decrease the vascularity of the part and to lessen the amount as well as to diminish the toxic quality of the thyroid secretion. When we consider the pathology of the gland and the action of radium, it would seem to have an assured place as a remedial agent. Bearing in mind that there is a proliferation of the glandular cells, deposits of lymph tissue through the thyroid, an enlarged and active thymus and lymph nodes, we conclude that the disease is not confined merely to the thyroid gland.

When the rays are applied to a blood vessel, there is a swelling of the tunica intima followed by an obliterating endarteritis in the smaller vessels, and a diminution of the calibre of the larger ones. Whether the toxic secretion is due to the additional blood supply or to the activity of the new-born cells in the gland, or to both, it will be affected by the radium action. The thymus and lymphatic glands are also rayed. The radiumizing of the thyroid and its correlated thymus and lymphatic glands accounts for the success in this form of treatment. The mere surgical removal of the thyroid alone will still leave unremoved affected tissue in the other glands. The beneficial effects observed in these cases are the slowing down of the pulse rate from twenty-five to thirty beats and marked reduction of the nervous symptoms. The gland usually diminishes in size. The tremors also disappear entirely and the patients gain in weight and general well-being. If exophthalmus is present, it is usually the last symptom to disappear.

There is no doubt but that radium has a wide field of usefulness in medicine, the value of which can best be estimated only after a painstaking collection of data. It has already passed the experimental stage, and richly deserves recognition in cases to which it is best adapted. It is no cure-all, but merely a therapeutic agent which should be used in connection with other well-established methods of treatment. Experience has shown that it increases the permanent benefits obtained by surgery, converts inoperable into operable cases, and materially relieves the sufferings of hopeless victims of some diseases.

1008 St. Johns Place.

AN IMPORTANT FACTOR IN THE USE OF PROTARGOL IN GONORRHEA.

By MAX HUHNER, M.D.,
NEW YORK.
CHIEF OF CLINIC, GENITOURINARY DEPARTMENT, MOUNT SINAI HOSPITAL DISPENSARY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE; MEMBER, AMERICAN UROLOGICAL ASSOCIATION, ETC.

It is now over ten years since I wrote an extensive article[1] on the diagnosis and treatment of gonorrhea, in which I strongly recommended the use of protargol.

Since that time there have been added to the therapeutic list many new preparations and chemicals both here and abroad. Many of them have been brought forward by prominent specialists and scientific institutions. I have tried most of them and have also watched with keen interest the trial of some of them by others, and, at the same time have followed up the literature on the subject. During these years I have noted the rise and decline in their popularity, until now, many, which had been heralded as the "ideal," have completely vanished from our therapeutic list.

I must confess, however, that after extensive trial, I still find protargol the best injection material we have at present. It gets rid of the gonococci more certainly that any other drug. It is true I have had my disappointments with it at times also. Every once in a while I come across a case of gonorrhea, in which gonococci of the particular strain are what I would call "protargol-fast." By which I mean, that protargol has absolutely no influence on them, the gonococci continuing to appear in large numbers in the discharge in spite of prolonged use of protargol. Such cases, however, are the exception. In the large majority of cases we can be certain that the gonococci will disappear from the discharge, even though the pus cells are not diminished. In many cases the visible discharge lessens or disappears with the disappearance of the gonococci, but in other cases, while the discharge continues the same, or may even increase, the gonococci disappear.

The main factor that has caused the popularity of many of the other silver preparations was the fact that they were not irritating to the urethral mucous membrane, and could be employed in much stronger solutions than protargol. While this property is of extreme value in the treatment of gonorrhea, I have found, however, that these preparations do not cause a disappearance of the gonococci with any amount of certainty, which, after all, is the main desideratum.

With a view of overcoming the irritation that sometimes follows the use of protargol, especially in stronger solutions, I experimented with various methods, until finally, several years ago, I discovered that by simply dissolving the protargol in physiological saline solution instead of distilled water, we could use very strong solutions (2 per cent.) with very little burning and in many cases without any increase of the urethral discharge, in some cases even a diminution. Of course I do not start with a 2 per cent. solution, but gradually work up to this strength, but strength for strength the saline solution of protargol is far less irritating than the distilled water solution.

I did not wish to publish this fact until I had a sufficient number of clinical cases to back up my observation, but when I was ready to publish it I found that a German professor had hit upon the same point about the same time and had published it in an extensive article.[2] This, therefore, precluded my publication of my experience as original.

I find, however, that even at present, many prominent specialists are not aware of this advantageous method of administering protargol, and a search through our most modern text-books on gonorrhea also fails to find any mention of this fact. Stating this to the editor of a prominent New York medical journal, I was advised by him to publish it. In writing prescriptions or in making it up for home use, all that is necessary is to substitute physiological saline solution for distilled water.

Services to Employees by Agreement with Employer—Compensation Cannot Fix or Enforce Fee of Physician, Who May Sue at Common Law.—In an action by a physician to recover the reasonable value of professional services he rendered at the request of the defendant company's superintendent to several of its employees, who were injured in the course of their employment, the defendant contended that under the Workmen's Compensation Law the plaintiff's exclusive remedy to recover the money value of his services was by application to the Industrial Commission, upon whom the law imposed the duty of fixing the plaintiff's fees. There was no dispute as to the rendition of the services, nor as to their reasonable value. The Compensation Law requires that an injured employee be given necessary medical services when injured in the course of his employment. That duty primarily falls upon the employer. If he refuses the employee's request for such aid or neglects to furnish the proper service, the employee may select his own physician. Manifestly, therefore, it was held, the defendant here was legally obligated to furnish the services to its injured employees for the value of which the plaintiff sought to recover. Could the plaintiff enforce his claim by an action at common law, or is he by statute law restricted to an application before the Industrial Commission for the fixation of his fees? The court found no authorities on the point, and was cited to none. It was held that the sentence in section 13, providing that, "All fees and other charges for such treatment and services shall be subject to regulation by the commission as provided in section 24 of this chapter, and shall be limited to such charges as prevail in the same community for similar treatment of injured persons of a like standard of living," has reference only to fees and charges incurred by the workingmen for medical treatment where the employer refuses or neglects to provide such treatment. Section 24 provides for the approval of the value of the services by the commission and the inclusion of the charge as part of the award, showing that it is the charge incurred by the employee, and not the employer, that is subject to regulation by the commission. "No attempt to regulate private arrangements entered into between the employer and the physician he might select is either expressly made or by implication to be spelled out of its provisions, and wisely so, for in no way could that be a matter of public concern. Nor is there any plan or schedule set forth for enforcement thereof. Recourse to a court of law therefore follows as the sole remedy, in the absence of a proper, expressed, and comprehensive provision for enforcement under the act. It is clear, therefore, that where the physician's claim is based solely on an agreement with the employer, and is not a part of the injured workman's claim for compensation, the compensation commission is without legal authority to fix the fee and enforce it, and the physician still retains his right to prosecute his claim in a common law action." Judgment for the plaintiff was therefore affirmed.—Feldstein v. Buick Motor Co., 187 N. Y. Supp. 417.

CONGENITAL AND OTHER LESIONS OF THE FEMALE GENITALIA IN THE INSANE.

LESIONS of the genital organs are frequent in insane females. Verhaeghe, at the Bailleul Insane Hospital, France, found that 73 per cent. of the patients presented some type of such lesion, and he suggests that a gynecological examination should always be made when insane patients are admitted to hospital. Congenital defects of the genitalia are more frequent in the insane than in females mentally normal, according to Verhaeghe's statistics. Out of a total of one hundred and thirty patients examined five presented uterine or vaginal congenital defects. Gynecologists, on the other hand, give much lower percentages, their figures being derived from mentally normal women. The congenital defects consist of single or multiple transverse septa, complete or incomplete, of the vagina and stenoses occupying a short length of the vagina, annular or diaphragmatic in type, and usually seated at the junction of the upper with the middle third of the canal. Fetal inflammation, persistence and union of the epithelial folds so evident at the onset of intrauterine life, or a strangulation of the vagina from a tardy development of the pelvic floor have all been invoked for explaining these congenital defects. Absence, imperforation, and abnormal situation of the vagina are also met with in the insane, as well as double or bicornate uterus, or absence or rudimentary state of the organ. All these defects are explained by a fusion of the two ducts of Müller, and the manner of production of these lesions represents a developmental defect that would naturally be more frequently met with in degenerate females, occupants of insane hospitals. The five cases mentioned by Verhaeghe presented an arrested development of the intellectual faculties even to the extent of profound imbecility. Rivalta has also reported four cases of congenital defects of the vagina, and in three of these patients mental degeneracy was manifest.

Briefly, these defects should be regarded as true genital stigmata of mental degeneration, and this is also the opinion expressed by Raffegeau, who points out that the medicolegal examiners and alienists should never neglect examination of the genital organs, and when congenital defects are found either in the male or female the subject should be suspected of mental degeneration unless the contrary can be proved.

Noninflammatory lesions of the uterus or adnexa may by various mechanisms react upon the cerebral functions, keep up delirium, giving it a new direction, and sometimes even being the cause of its outbreak. Surgical treatment is required as mental therapeutics in every case in which there is not an evident disproportion between the extent of the lesions and the local sensations complained of by the patient. Inflammatory lesions of the organs of generation are particularly frequent in insane women, Verhaeghe finding the proportion of 353.84 per cent. in his cases. In 33 per cent. these lesions had resulted from a recent delivery, and in puerperal insanity uterine infection is the rule. The frequency of the lesions and the happy effect of treatment in these circumstances lead to the supposition that infection occupies the foremost place in the pathogenesis of puerperal insanity. When the lesions are due to some other etiological factor their treatment does not give such good results from the viewpoint of the mental affection, a fact that can be explained either because the lesions developed after the mental process or because when preceding these they were of too long standing when treatment was undertaken.

Menstrual disturbances are also common in the insane. In epilepsy the menses do not often appear to have a marked influence upon the attacks and in many subjects the attacks become more frequent after the menopause. General paralysis usually causes amenorrhea, while the reestablishment of the menses frequently coincides with the occurrence of a remission in the mental process. In about 33 per cent. of the cases, early dementia accompanies suppression of the menstruation, while amenorrhea is present in about the same proportion in melancholics. In maniacal cases the menses are usually regular, and this is also the case in the delirium of persecution.

PROGNOSTIC VALUE OF THE LEUCOCYTIC COUNT AFTER SURGICAL OPERATIONS.

ALL surgical interferences, aseptic or otherwise, are usually followed by a neutrophile polynuclear hyperleucocytosis which appears on the second day following the operation and usually disappears by the tenth day. In some cases this hyperleucocytosis attains its maximum the day following the operation—17,000 to 25,000 leucocytes and 82 to 91 per cent neutrophile polynuclears—a maximum followed by a gradual drop to the minimum on the tenth day. This curve coincides with a pulse and temperature of favorable augury and clinically the case undergoes an aseptic evolution. This polynucleosis has the same prognostic value as the pulse and temperature curves. In other cases the polynuclear hyperleucocytosis occurs tardily after the operation and in these circum-

stances it never has the same numerical value, ranging from 75 to 80 per cent., and coexists with a normal pulse and temperature. In these cases there is some suppuration during their progress toward recovery. There are also cases in which polynuclear neutrophile hyperleucocytosis attains its maximum on the day following the operation, but with a very high pulse rate. In these circumstances the outcome is apt to be unfavorable, as general infection ensues. Therefore, a high pulse rate with an early and high leucocytosis is of bad prognostic import. In one series of cases studied by Bouchez, he found a notable decrease in the percentage of eosinophiles the day following the surgical intervention, although they did not completely disappear, and this was followed on the third day by a very marked eosinophilia—5 per cent. The patients in this series had an aseptic recovery and the prognosis was favorable. In this respect it should be remarked that the more favorable the outcome the higher will be the eosinophilia after the operation. Therefore, it is an excellent index to recovery.

When there is complete absence of this element in the blood after a surgical operation the outcome of the case will certainly be less fortunate. Suppuration will be accompanied by delayed and low (3.7 per cent.) eosinophilia, and in fatal cases the eosinophiles will not appear after operation. In those cases in which a relatively high percentage of mononuclears is present the prognosis is not favorable, suppuration or septicemia ensuing. In Bouchez's experience, the basophiles acted in about the same way as the eosinophiles. This observer is therefore of the opinion—all due reserves being made—that the curve of polynucleosis and eosinophila compared with that of the pulse is an excellent and ready means of making a postoperative prognosis. The temperature curve is perhaps less sure, because he has had the opportunity of studying cases in which the termination was favorable in spite of a high temperature where the polynucleosis continued to retrogress.

The leucocytic curves indicate the intimate reactions of the organism with the greatest exactitude when their study is carefully carried out. Generally speaking, the intensity of hyperleucocytosis will be in direct ratio to the intensity and gravity of a given affection. A relationship of the same order is established between the degree of the polynucleosis and the gravity of the disease. In affections with a polynuclear leucocytosis, an excess or absence of this reaction may be taken as an index of the gravity of the morbid process; therefore, great reserve should be exercised in respect to the prognosis when applying the leucocytic count. In smallpox in particular, an enormous drop in polynuclears is an index of a fatal outcome. In other infectious diseases eosinophilia serves as an element in the prognosis. Piechi, Pieraccini and Noegeli have shown that in typhoid fever the persistence of eosinophiles at the height of the disease and their reappearance in the second and third phase of the process indicate a favorable prognosis. The blood-count after operations is useful in order to arrive at a prognosis in many cases where this is doubtful.

FORENSIC SIGNIFICANCE OF TATTOOING.

Tattoo marks are often of service for identification but only within limits. To have an anchor tattoed on the back of the hand, for example, would be indecisive. On the other hand, a large ornamental design with an inscription would possess considerable significance. If other individuals showed similar patterns this similarity would not extend to identity of location, measurements, etc. Tattoo marks have identified individuals after decomposition of the cadaver. Lombroso cited an old custom prevalent in his native neighborhood of tattooing foundlings. The question of disappearance of tattoo marks in connection with identification is an old one in the courts. It is accepted by jurists that they never vanish spontaneously, although this must be qualified by the nature of the substance used. Cinnabar marks fade to such a degree that we may visualize their disappearance. Marks produced by ordinary writing fluid can certainly disappear, although material of this kind is not in demand for tattooing. The most famous court case was the Tichborne claim, the pretender having been shown to be without the tattoo marks known to have been present on the true Tichborne.

Cattani, who discusses this subject in the *Schweizerische medizinische Wochenschrift* for March 10, 1921, li, 10, says detattooing is a difficult one to generalize on. As a rule, efforts of this kind—and very many are in use—fail, although there are methods in which the tattoo marks could be replaced by scar tissue, or excised. At present there are methods by which the most of the pigment can be removed, but while this might be called a cosmetic success, the traces which would remain might make or upset an identification.

The motive for tattooing may have forensic significance; for while propinquity explains most of the cases among sailors, tattoo marks in criminals may have a deeper motivation, and Lombroso built up a theory of atavism, a persistence of the savage tendency to symbolize something, express one's personality, etc. According to this view, the choice of pattern is an index of the psyche. The author agrees with Leppmann that tattooing has no deep anthropological significance, and that the motivation comes entirely from environment. Otherwise we would find men in distant parts of the world, belonging to distinct nationalities, using similar patterns in response to endogenous symbolism. Much of the choice is left to the professional tattooer, who is influenced by a variety of motives. Thus he may excel in a certain design and advocate it for that reason. To find a crucifix tattooed on the chest of a man may not argue any devotional im-

pulse; perhaps beside it there may be seen the figure of a nude woman. Neither can occupation be predicated from tattoo marks. The author makes no allusion to the systematic or formal tattooing of the Paris Apache. Self-tattooing is not uncommon and may sometimes be suspected from the location, which would necessarily be restricted. The author, like others, has seen cases in which a subject was tattooed against his will. This has been done by intimidation or violence, but also during insensibility. In regard to the consequences of tattooing on the health the practice has conveyed both syphilis and tuberculosis, to say nothing of causing phlegmon, gangrene, erysipelas, and keloidal scars.

DUALITY OF THE SYPHILIS VIRUS.

THE growth of the problem of unicism and duality has been gradual and the evidence cumulative. For many years we have known that paresis is a relatively new disease and one which is peculiar to civilization. Fournier used to speak of the extreme mildness of the course of syphilis in the tabetic and paretic, which very mildness, he thought, caused treatment to be largely ignored. But it was shown that paresis could follow well treated syphilis. Then conjugal syphilis came to the fore and it was shown that a neurotropic syphilis in the husband often caused the same type in the wife. To this may be added the celebrated case of the woman who infected five of her lovers, all of whom died of paresis within 20 years. Another document in support of dualism is the resistance of paresis and tabes to treatment.

Mirande, who gives the latest exposition of the status of this subject in the Syphilis number of the *Journal de médecine et de chirurgie pratiques* for December 10, 1920, xci, 23, says that after the discovery by Noguchi of the spirochete in the brain of paretics an era of experimentation was inaugurated. The first experiments showed that the treponema which is found in the venous blood of the paretic can transmit syphilis to the rabbit. Comparison of the course of this type of rabbit syphilis with the ordinary type shows differences which involve the time of incubation, appearance of lesion, evolution, and virulence. The orginal or dermotropic virus exhibits a necrotizing and sclerosing power not possessed by the neurotropic virus which causes mild papulosquamous lesions. The dermotropic virus also attacks the blood vessels. In human experiments on volunteers, inoculation of the neurotropic virus have been negative and this is true of the anthropoid apes. It also appears that after the cure of rabbit syphilis of the neurotrope type the animals can be readily infected with the dermotrope form, and rabbits immunized against dermotropic virus can also be successfully inoculated by the neurotropic virus.

At present the case for dualism appears to be complete, for there are many experiments that cannot for want of space be recapitulated here. The differences between the two syphilis spirochetes may be as marked as those between the spirochetes of Dutton and Obermeier, causes respectively of African and of European recurrent fever. This throws no light on the origin of the neurotropic form but the evidence points to evolution of the latter from the dermotropic form by a process of adaptation in which an increased sensibilization of the nervous centers may play a part. Once the neurotropic strain has developed it behaves as an autonomous organism causing a mild type of syphilis of the skin, mucosæ, and viscera. The refractoriness in man of neurotropic syphilis to treatment is inexplicable by animal analogy, for in rabbit syphilis the neurotropic disease readily responds to organic arsenicals.

ENDEMIC SYPHILIS IN BOSNIA.

ONE of the greatest stumbling blocks to the theory of the modern origin of syphilis is its failure to explain the so-called endemic syphilis which has often occurred side by side with the ordinary venereal type, completely ignored by the syphilographers of the day. This was well illustrated in Ireland. History shows that venereal syphilis was very slow in getting a foothold into the interior of this country. For centuries perhaps it was found only in the ports and vicinity. But there was an affection known as "button scurvy" which appears to have been known from time immemorial. The Dublin school of syphilographers with all their experience and acumen failed to note the identity or even any resemblance with venereal syphilis until one of their number, Porter, grasped the fact after much research that they were one and the same. Many years before this recognition Colles, Carmichael, and others described and even in one case illustrated "button scurvy," which representation looks syphilitic enough to us to-day even in the crude colored plate. Failure to recognize it as syphilis was due to the absence of venereal contacts and primary lesions on the genitals, occurrence in family incidence among the poor but virtuous peasantry, knowledge of similar endemics (like "sibbens" in Scotland) among rural peoples, etc. In the *Schweizerische medizinische Wochenschrift* for June 16, 1921, li, 24, we find that identical conditions still obtain in Bosnia, as they have for many years past. Side by side with ordinary venereal cases with primary lesions are seen exquisite familial cases in endemic incidence. In one locality 230 such families were found, all infested with the disease. In one family of eight all presented buccal lesions. Hereditary cases are so rare that they may be regarded rather as belonging to venereal syphilis. These endemic cases respond quickly to treatment and no case of neurosyphilis or metasyphilis has ever been reported.

ETIOLOGY OF HERPES FEBRILIS.

THIS subject has recently assumed importance because of the results of certain laboratory investigations which seem to show an analogy between simple herpes and epidemic encephalitis. But Luger and Lauda, who discuss it in the *Wiener klinische Woch-*

enschrift for May 26, 1921, xxxiv, 21, do not allude to this relationship. Herpes febrilis now suggests an autonomous general infection of which ordinarily the skin lesion is the most constant or characteristic symptom. Something of the same nature is evident in herpes zoster. The bacterial flora isolated from the vesicles do not point to any one exciting cause. The authors examined the exudate in herpes febrilis due to the most dissimilar causes. In some cases the patients had ordinary colds, in others pneumonia and meningitis, and in still others there had been injections of therapeutic substances, as salvarsan, or ordinary milk. The results were flatly negative. The successful inoculability of the rabbit cornea with the contents of herpes vesicles is now discussed but despite the genuineness of this phenomenon no microorganism has yet been isolated. The authors have been unable to produce by this inoculation the general infection with lesions of the nervous centers described by some laboratory men (Kooy, Doerr). However, they announce one very striking find obtained as follows: The contents of an ordinary fever-blister or "cold-sore" two days old, were injected directly into a rabbit's veins. The animal became ill with a constitutional infection and succumbed in three days (incubation period ten days). An emulsion of brain and cord was now filtered through a Berkefeld and the filtrate injected into the veins of a second rabbit which practically duplicated the experience of the first animal. Thus far, therefore, the authors uphold the contention of their colleagues in this research.

News of the Week.

Typhoid Fever Outbreak Spreads.—The epidemic of typhoid fever in Burlington County, N. J., continues to increase, there being twenty-five new cases reported on August 30, with four deaths. Physicians and nurses of the State Department of Health are in charge of the situation and several Red Cross nurses are in the fever zone.

National Cancer Week.—The American Society for the Control of Cancer announces a seven days campaign to be designated "Cancer Week" from October 30 to November 5, 1921. The purpose of the movement is to reach as many persons as possible in the United States and Canada with the hopeful message of cancer control. In order to carry out the campaign the first step will be to effect a complete organization through the appointment of State Chairmen, who will see that a chairman of local committee is appointed for every community of five thousand population or more in his State. The chairmen of the local committees will in turn select their committees. The campaign will be carried on through three main activities, namely, lectures, literature, and publicity. It is expected that health departments, medical societies, medical schools and colleges, nurses' training schools, nurses' organizations, schools for health officers, insurance companies, and the Federation of Women's Clubs will cooperate in carrying out the activities planned. A feature of the campaign in the larger cities will be demonstration and diagnostic clinics in which an effort will be made to interest all physicians in the vicinity. The American Society for the Control of Cancer will provide literature for distribution at the lectures. It will also provide outlines for lectures and suggestions for press publicity. The support of the entire medical profession is solicited in order that the humanitarian purposes of the campaign may be realized in as full a measure as possible. The headquarters of the Society are at 25 West 45th Street, New York City.

An Invention for Photographing Surgical Operations.—According to reports of the lay press from Berlin a new apparatus has been devised which can be fitted to the ceiling of the operating theatre and set in motion from below. While an operation is being performed it enables films to be taken showing the minutest details of the operation. After a demonstration in Berlin of what can be done with this device, it was announced that the German Government was considering establishing a technical cinematograph institute in Berlin and a special lectureship in cinematography.

Hospital Notes.—Plans have been formulated looking to the expansion of the Elliott Hospital, affiliated with the University of Minnesota. The hospital at present has a capacity of approximately two hundred beds which will be expanded to four or five hundred beds.

A permit has been granted to erect a new laboratory as a part of the New Haven Hospital. The entire cost of the new building and the equipment will be about $55,000.

A new hospital is to be erected in South Lawrence, Mass., under the direction of the Sisters of Charity of the Order of the Grey Nuns.

Occupational Therapy at Bellevue Hospital.—According to a statement issued by the Hospital Occupation Committee, three hundred and fifty patients a month are brought back to usefulness and produ tive activity by its teachers in the wards of Bellevue Hospital, New York. The results achieved at Bellevue Hospital afford a convincing demonstration of the value of occupational therapy as an aid to the recovery of patients in a large city hospital. Patients who are experiencing its benefits range from those who have had amputations, to those who are temporarily deranged, or are the victims of tuberculosis, or just breakdowns of body and spirit. Six paid teachers and several volunteers have been giving the instruction in occupational therapy with the full cooperation of the hospital authorities, who give the work their most emphatic endorsement. Dr. George O'Hanlon, General Medical Superintendent, states that "the work has been most beneficial to the entire hospital. The Hospital Occupation Committee is asking for $4,000 with which to continue its work.

Philippine Lepers Without Medicine.—President Harding's mission of inquiry to the Philippines, after a visit to the leper colony on the Island of Culton, reports that there are about 5,000 lepers on the island. The report shows that a lack of funds is preventing the treatment of more than 300 of these with chaulmoogra oil. Aside from these the remaining lepers are said to be practically without treatment.

Ship Passengers Protest Against Vaccination.—Passengers on the *Rochambeau* which reached here August 27 severely criticised the immigration regulations which forced them to be vaccinated before they were allowed to board the ship in Havre on

August 10. The ship is what is known as a "one cabin" vessel and everybody is considered in the light of a second cabin passenger and has to undergo vaccination. A physician who refused to submit to vaccination because he said it was being improperly done was told he must appear before the American Consul and sign a release absolving the line and the surgeons of blame in case pestilence broke out.

Dr. Calmette Fights Antivivisectionists.—Dr. Calmette, director of the Pasteur Institute, has taken up the cudgels against antivivisection, declaring that its advocates are threatening the prestige of the medical and scientific world in France. Antivivisectionists are said to have raised a fund of several million francs for propaganda in France, Austria and Italy.

French Birth Congress.—The Bordeaux Chamber of Commerce, with the General Council of the Gironde, and the municipality of Bordeaux, have organized in that city the Third National Birth Congress, to be held September 22-26, 1921. The Congress will be under the official patronage of the President of the Republic, and the Chairman of various Chambers of Commerce, and will comprise five sections—religous activities, instruction, hygiene, professional activities, and legislation. The two former birth congresses, one held in Nancy in 1919 and the other in Rouen in 1920, emphasized in a striking manner the necessity of solving the problem presented by the lessening of the French population.

Professor Tuffier, the well-known French surgeon, has been invited to deliver the inaugural address at the opening of the University of Pekin Medical College in September. His subject will be "Study of Surgical Septicemias and their Treatment." The lecture will be on September 17 and on the three ensuing afternoons he will hold surgical clinics.

Dr. Marie M. Long has been placed in charge of the newly established division of child hygiene of the Department of Health of Memphis, Tenn.

Dr. Harlan L. Paine, for the past year executive officer of the Boston Psychopathic Hospital, has been appointed superintendent of the Grafton State Hospital.

Dr. Edward A. Spitzka of the Neuro-Psychiatric Section, U. S. Veterans' Bureau, Washington, D. C., has been appointed Chief of the Medical Rating Section in the Second District Branch (New York) of the U. S. Veterans' Bureau.

Dr. Mark Cohn has removed his office to 1802 Crotona Avenue, New York City.

The Annual Conference of Sanitary Officers and Public Health Nurses of New York State will be held at Cornell University, Ithaca, September 13 to 15, under the auspices of the State Department of Health. The conference will be opened by Dr. Hermann M. Biggs, Commissioner of Health, who will introduce Governor Nathan L. Miller. Following the Governor's address, Acting-president A. W. Smith of Cornell will welcome the delegates to the convention. Dr. Hugh Cumming, Surgeon-General of the United States Public Health Service, will represent the Federal Government, and Miss Ella Phillips Crandall, the National Organization for Public Health Nurses. Representatives of a large number of other health organizations will be present. On Tuesday evening the delegates will be shown a number of new health films. On Wednesday afternoon the Ithaca Board of Commerce will give a reception to wives of delegates and other visiting ladies. On Wednesday evening the annual dinner will be held.

Obituary Notes.—Dr. WILLIAM CURTIS DEANE of New York City and Douglaston, L. I., died at his home in the latter place on August 29, at the age of sixty-five years. He was graduated from New York University Medical School in 1884.

Dr. MATTHEW H. CRYER, Professor Emeritus of Oral Surgery at the University of Pennsylvania, died August 11, at the age of eighty-one years. He was graduated from the University of Pennsylvania School of Medicine in 1877.

Dr. SAMUEL B. WHITTINGTON, head of the Sprague Institute, New York, died at his home in Kew Gardens, L. I., on August 16, at the age of fifty-two years. He was graduated from the University of Southern Illinois.

Dr. HENRY W. MINDEL, for forty-two years a practitioner of medicine in Philadelphia, died in Wildwood, N. J., on August 14, at the age of seventy years. He was graduated from Jefferson Medical College in 1873.

Dr. THOMAS H. LEIDY of Reading, Pa., a graduate of Jefferson Medical College in 1869, died on August 14 at the age of seventy-six years.

Dr. PETER R. HATCH of Youngsville, N. C., a graduate of the College of Physicians and Surgeons, Baltimore, in 1883, died on July 30.

Dr. EDWIN ATLEE HAMBRIGHT, a graduate of Hahnemann Medical College, Philadelphia, in 1874, died at his home in that city on August 10, at the age of seventy-five years.

Dr. PHILIP Y. EISENBERG of Norristown, Pa., for ten years president of the Norristown Hospital and a former president of the Montgomery County Medical Society, died on August 14 at the age of seventy-five years. He was graduated from the University of Pennsylvania Medical School in 1873.

Dr. W. J. REDDITT of Carrollton, Miss., Louisville, Ky., Medical College in 1872, died on August 13.

Dr. ALEXANDER MITCHELL LOEWENSTEIN of Troy, N. Y., died in Cleveland, Ohio, on August 10, at the age of thirty-six years. He was graduated from the Albany Medical School in 1908. He served as a captain in the World War, being stationed in Russia for a time.

Dr. W. E. BROWN, a retired physician of Fort Worth, Texas, died on August 7. He was a graduate of Washington University Medical School, St. Louis, in 1869.

Dr. FLOYD W. MCRAE, Sr., of Atlanta, Ga., a graduate of the Atlanta Medical College in 1885, died suddenly on August 13, at the age of fifty-nine years.

Dr. JUSTIN LOWE JACKSON, a graduate of the Southern Botanico Medical College, Macon, Ga., in 1902, died at his home in Savannah on August 11, at the age of forty-six years.

Dr. JOSEPH C. WINANS of Belleville, N. J., a graduate of New York University and Bellevue Hospital Medical College in 1905, died on August 9, at the age of forty-two years. He served as a captain in the Medical Corps of the Army during the late war.

Dr. EDWIN W. MOORE of San Diego, Calif., who formerly practiced medicine in Franklin, Pa., died of pneumonia in a New York Hospital, about August 3. He was a graduate of the University of Wooster Medical Department, Cleveland, Ohio, in 1869.

Dr. JOHN C. FELTY, retired, formerly a member of the medical staff of St. Luke's Hospital, Bethlehem, Pa., died at his home in Gettysburg, Pa., on August 7, at the age of seventy-two years. He was graduated from the University of Pennsylvania Medical School in 1873.

Dr. ELMIRA Y. HOWARD, believed to be the first woman who practiced medicine west of the Alleghany Mountains, died in Covington, Ky., on August 8, at the age of eighty-one years. She was graduated from the New York Medical College for Women in 1868, and began the practice of medicine in Cincinnati in 1869.

Dr. JAMES HETHERINGTON MACKINTOSH of Westwood, N. J., a graduate of Bellevue Hospital Medical College in 1872, died on August 5, at the age of eighty-four years.

Dr. HENRY A. HENRIQUES, president of the State Hospital for Tuberculosis at Morris Plains, N. J., died suddenly at his residence in Morristown, on August 19, at the age of sixty years. He was graduated from the College of Physicians and Surgeons, New York, in 1883. He was a former president of the Morris County Medical Society and for many years a visiting surgeon to the Memorial and All Soul's Hospitals of Morristown.

Dr. MELANCHTHON SAYRE AYERS, a graduate of the Long Island College Hospital in 1871, died at his home in Teaneck, N. J., on August 18, at the age of seventy-four years.

Dr. EBENEZER ALDEN DYER of Whitman, Mass., a graduate of Bellevue Hospital Medical College in 1882, died on August 5, at the age of sixty-five years. He was a member of the Board of Health of Whitman and in 1906 a member of the Massachusetts State Legislature.

Dr. ROBERT T. FRENCH of Rochester, N. Y., died suddenly of heart disease on August 11, at the age of fifty-seven years. He was graduated from the Buffalo Medical College in 1888. He was a member of the American Medical Association and the Rochester Academy of Medicine.

Dr. FREDERICK D. VANDERHOOF of Phelps, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1864, died on August 6 at the age of seventy-eight years. For several years he served his town as health officer. He was at one time president of the Ontario County Medical Society.

Dr. JOHN HENRY OSWALD MARLING of Toronto, Canada, died suddenly in Baltimore on August 1, at the age of fifty-six years. He was graduated from Trinity Medical College, Toronto, in 1888.

Dr. HIRAM M. HILLER, formerly of Chester, Pa., died at Bellefonte, Pa., on August 9, at the age of fifty-four years. He was graduated from the medical department of the University of Pennsylvania in the class of 1891. He was a member of the Delaware County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. EDWIN ATLEE HAMBRIGHT died at Philadelphia on August 10, at the age of seventy-five years. He was graduated from Hahnemann Hospital and Medical College, Philadelphia, in 1874.

Dr. GEORGE STEDMAN of Boston, for twenty years medical examiner for Suffolk County, died on August 16, at the age of seventy-three years. He was graduated from Harvard College in 1871 and from Harvard Medical School in 1875. He was a member of the American Medical Association, the Massachusetts Medical Society, and the Massachusetts State Medico-Legal Association.

Dr. CHARLES E. A. LAFERRIER of Woonsocket, R. I., a graduate of Victoria University Medical Department in 1887, died on August 15.

Dr. DANIEL W. HARNER of New Holland, Pa., a graduate of the Cleveland University of Medicine and Surgery in 1878, died after a lingering illness in Atlantic City on August 14, at the age of sixty-six years.

Dr. HANSELL CRENSHAW of Atlanta, Ga., a graduate of the Atlanta College of Physicians and Surgeons in 1900, died July 30, at the age of forty-four years. He was at one time professor of chemistry at the Atlanta School of Medicine and later was assistant professor of psychiatry at Emory University Medical School. He served overseas in the Medical Corps of the Army during the late war.

Correspondence.

HAZARDOUS OPERATIONS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Of course, there are degrees and differences among these. In the case of a young person, strong in health and limb, they may and should be undertaken when medical treatment has proved unavailing.

When, however, the patient is already well on in years and even when good physicians and the best care have failed to bring relief, should surgeons operate? If there is a fair chance of cure, or if not, of relief from pain and suffering, not to speak of invalidism, an operation may properly be done. When, on the other hand, the probabilities are very largely against any favorable outcome to the patient in any way, I protest against operations. Too many are done, nowadays, which have no justification in my eyes. They cannot hope either to cure or relieve, and if they do not, the patient is again compelled to take medical remedies, with the added trouble or discomfort which results as a rule from an operation. Further, I object to a patient being transported to a hospital for operation, when it can really be equally well done at home, provided the patient's feelings and comfort are duly considered by the surgeon.

The claim that there is greater comfort to the patient in an operation at a hospital, is often delusory, especially if the patient has abundant pecuniary means. The effect, mentally and bodily, upon a patient's being taken from his home surroundings to a place strange to him, is often pitiful and disastrous.

Besides, while some hospitals are new, well constructed, properly ventilated, and kept aseptic, others are not. Therefore, home is a much better place for the patient during and subsequent to the operation.

These, I know, are not prevalent opinions, but they are true and correct, as I believe. Be it understood that I am not urging that poor men and women should be kept at home for severe operations. This should not be, because things required cannot be forthcoming, and sentiment should be relinquished in favor of what is reasonable.

My thoughts are dictated by not a few cases of wealthy patients, operated on at hospitals, when they should have been kept at home. Death sometimes occurs a few days subsequent to the operation at the hospital, whereas if the patient had been operated on in his own home, I believe he might have recovered.

BEVERLEY ROBINSON, M.D.

123 EAST 35TH STREET, NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, August 17, 1921.

Smallpox Outbreak in Great Britain.—Smallpox has broken out on a somewhat considerable scale in the midland district of England. While, of course, every precaution is being taken to guard against the disease spreading, a disquieting feature of the situation is the enormous growth in the number of exemptions from vaccination since the passing of what is known as the "John Burns Act" in 1908. A medical expert of the Ministry of Health explained in an interview to a representative of the *Daily Telegraph* published in its issue of August 16 last that the number of births registered in England and Wales during the year was 929,882, and in that year 644,366 infants were vaccinated, that is to say, the percentage of vaccinations to births was 71.4 per cent. In the same year 39,925 infants were legally exempted from vaccination. In 1919, the last year for which the corresponding figures are available, there were 691,370 births and 251,029 infants vaccinated, equivalent to 40.6 per cent., while 277,558 infants were legally exempted. The official returns show very clearly that as soon as the vaccination act of 1907 came into operation the number of exemptions immediately jumped from 76,709 in 1907 to 160,350 in 1908, while the percentage of vaccinations to births dropped from 70.9 to 63.2 per cent. By 1914 the number of exemptions had reached 320,421. During the war years there was a slight decrease, due in part, of course, to the fact that the birth rate showed a considerable decline, but since the armistice the number of exemptions has steadily mounted. This medical authority went on to say that the public sometimes forgot the extent to which England suffered from smallpox in the days before Jenner discovered the efficacy of vaccination. In Chester, for instance, in the year 1774, an epidemic of smallpox occurred, and out of a population of 14,713, 1,202 persons were attacked by the disease, and of those, 202, all children under ten years of age, died. At Warrington in the previous year, another epidemic of smallpox was responsible for 211 deaths in a population of 8,000, and again the highest mortality was among children under nine years of age. This was due to the fact that the susceptible population would be composed mainly of those who had been born since the previous epidemic. Thus the incidence of the disease would fall mainly on children, for it is a remarkable fact that one attack of smallpox renders a person immune from subsequent epidemics. It is not generally known that in 1721 many persons used to inoculate smallpox artificially in order to produce a mild attack at a convenient time rather than run the risk of a severe attack at an inconvenient time. This, of course, was made illegal by Act of Parliament in 1840. Asked whether the Ministry had power to enforce vaccination in areas where a serious outbreak threatened, the official said they had not, but the Ministry of Health were pressing the need of a voluntary revaccination very assiduously. The experience of the last century, he said, had shown that vaccination did not necessarily protect every life. It was probable that its tendency to modify an attack of smallpox never entirely disappeared, but its protective power waned with the lapse of time. It could, however, be stated that although vaccinated persons under ten years had contracted smallpox, the attacks had been very mild and fatal issues had rarely occurred. For the great majority of persons it would suffice to renew vaccination at the end of ten years. At the present time it was certain that a greater number of the male population between the ages of 20 and 40 had been revaccinated than would have been the case in former years. The position, therefore, was that the whole adult population was better protected against an attack of smallpox than had previously been the case. As regards the child population, however, only about one-half the children under ten years of age had been vaccinated.

Second Annual Report of the Ministry of Health.—The second annual report of the Ministry of Health has just been issued. With regard to the question of international health the report runs as follows: "The establishment by the League of Nations of an International Health Organization, which was approved at the first session of the assembly of the League in December, 1920, is destined to forward the work of safeguarding the health of the people in this and other countries in a number of directions. The organization will have, among the functions specifically assigned to it, the duty of bringing administrative health authorities in different countries into closer relations with each other, and of securing not only the rapid exchange of information but the adoption of swift and simple methods of action against the attacks of diseases which transcend national boundaries. Pending the effective establishment of the new organization, a provisional committee, on which the department is represented has been set up. The assistance of the Council of the League has already been invoked in assisting the Polish health authorities with the financial and sanitary measures required to check the spread of typhus in Poland. It is pointed out that so far as tuberculosis is concerned a considerable decrease in the number of deaths from tuberculosis in England and Wales occurred in the year 1919 as compared with previous years, and a further decrease in the year 1920 is to be noted.

The number of treatment centers for venereal

diseases opened during 1920-21, and the number of patients dealt with for the first time increased by 23 and 7,000 respectively. The attendances at centers rose to 1,489,000, as against 1,003,000 in 1919, and 488,000 in 1918. The amount of the grants in aid of venereal diseases schemes paid during the year was £327,596, or approximately £100,000 ($500,000) more than in 1921. The report goes on to say that at four treatment centers the number of attendances during the year 1920 exceeded 60,000. It may be noted that more than 284,000 patients have been dealt with at the treatment centers between January 1, 1917, when the first centers were opened, and December 31, 1920, and that the total number of attendances during this period at the outpatient clinics has exceeded 3,156,000.

Dealing with maternity and child welfare, the report states: The number of centers rose during the year by 183 to a total of 1,780, 1,068 provided by local authorities and 712 by voluntary agencies; the health visitors at work increased from 3,000 to 3,215; a somewhat larger proportion of births in London and in county boroughs was attended during 1919 by registered midwives and their assistance is now estimated to be available to 68 per cent. of the rural population. The infant death rate fell from 89 per 1,000 births in 1919 to 80 per 1,000 births in 1920, the lowest point yet reached in the recorded figures for England and Wales. Under the Blind Persons' Act, 1920, persons so blind as to be unable to perform any work for which eyesight is essential, become eligible for old-age pensions at the age of 50.

About 12,300,000 people in England are now entitled to medical benefit under the National Health Insurance Acts. The annual cost of this service is about £8,000,000, of which nearly half is defrayed by the National Exchequer in the form of statutory contributions and special grants. Steps have been taken during the year to promote the efficiency of the treatment thus made available to insured persons, both by the appointment of divisional and regional medical officers, whose primary duty is to advise upon cases of incapacity for work referred to them either by approved societies or by insurance practitioners; and by the revision of the system of records of patients' illnesses kept by insurance practitioners with the main object of securing for clinical use a continuous history of such illnesses. With respect to tuberculosis notification it is pointed out that the provision of treatment for tuberculosis as a benefit under the National Health Insurance Acts has now been brought to an end. Insured persons will continue to receive domiciliary treatment from their insurance practitioners, but the responsibility for the provision of residential treatment for insured, as well as for non-insured persons now rests with local authorities and not with insurance committees. During the year capital grants of £275,609 were paid and loans of £378,320 were sanctioned in aid of the provision of sanatoriums and other institutions for the treatment of tuberculosis; approval was given to institutions containing 1,571 additional beds, 1,009 provided by local authorities and 562 by voluntary bodies. Over £900,000 was paid as grant in aid of the cost of maintaining institutions; the number of cases notified for the first time was 73,372, made up of 57,544 pulmonary cases and 15,488 non-pulmonary cases. The deaths from this disease, which in 1918 reached the figure, 58,073, were in the calendar year 1920, 42,545, pulmonary tuberculosis accounting for 33,469 of these deaths.

The most prominent feature of the report is the plea made at the outset for economy in public expenditure, and it is noticeable that although the mass of the population comprehend more fully than before the war the benefits conferred by general good health and are thus more favorable to projects for the extension of health services, at the same time it has become more and more evident that they are unwilling that such projects should be realized at the expense of the ratepayer and taxpayer. Conditions are not now propitious for carrying out ambitious and necessarily expensive schemes in behalf of the public health. The Ministry of Health have now grasped the fact that the temper of the public is such that no plans of a costly nature will be permitted at the present time. The following quotation from the report will show that the situation is understood by the Ministry "so long," says the report, "as the financial prospect remains unfavorable the department and the local authorities can profitably devote increased attention to the task of surveying the whole field of health services and health organization with a view of insuring that when the economic situation permits fresh progress to be made, whatever action is taken is based upon a mature and deliberate plan."

Of course, under present conditions this is the only way and moreover in the long run may prove the wisest way. No scheme will be undertaken without mature consideration. It must be borne in mind that the Ministry of Health up to the present time have been beset with difficulties. Sometimes their policy may have been indiscreet, but the population have not been educated as yet to a belief in the value of preventive medicine, which is the basis of a Ministry of Health's policy.

LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, Aug. 1, 1921.

Wounds of the Thorax.—Dr. Janssen, a Belgian surgeon, has recently given his statistics, based on a total of 326 cases, of wounds of the thorax treated by him during the war, to the Surgical Society of Belgium. Briefly in his experience wounds of the thorax in war are usually penetrating—64.7 per cent. being penetrating as against 35.3 per cent. parietal. Simple penetrating wounds are much more frequent than thoracoabdominal wounds, there being respectively 82.4 per cent. and 10.8 per cent. Thoracic wounds resulting in death from other lesions represent 6.8 per cent. In the category of simple penetrating wounds those with a closed thorax compose the vast majority, being 77.4 per cent., as against 10 per cent. of wounds with open thorax and 8.3 per cent. of wounds of thorax and mediastinum, while the nature of the wound was not determined in 4.3 per cent. of the cases. In the category of thoracoabdominal wounds, lesions of

the liver, spleen, or kidney represent 75 per cent., as against 19.6 per cent. lesions of the stomach and intestine, and 5.4 per cent. lesions of the diaphragm and peritoneum. The most common and at the same time most valuable symptom in this type of wounds is hemothorax; subcutaneous emphysema is frequent. Open pneumothorax presents a particularly dramatic symptomatology, while the diagnosis of a thoracoabdominal wound is difficult to make on account of the frequency of abdominal muscular rigidity in simple penetrating thoracic wounds. General emphysema is serious when it reaches the mediastinum. In Janssen's experience infected hemothorax is rare, the diagnosis of infection being made by the bacteriology and cytology of the collection.

The general treatment of closed thoracic wounds is abstention from operation with absolute immobilization of the patient, and operation will be indicated only when hemorrhage is going on or in the presence of a large piece of shell buried in the pulmonary parenchyma. Every open thoracic wound requires operation; the operative act should realize occlusion of the opening by suture or gauze plugging. The technique of thoracotomy for hemorrhage is a long incision, but with excision of a single rib, hemostasis by suture of the lung, with or without removal of the foreign body as indications may point, and hermetic closure without drainage. Mortality after gauze plugging of the thorax is 45.1 per cent., after suture, 40.8 per cent.; and cent. and 33.3 per cent. respectively. Abstention excluding deaths from some other lesion, 41.7 per from operation gives only 15.8 per cent. mortality, all cases being included. Thoracotomy reserved for cases of otherwise fatal hemorrhage gives a death rate of 83.3 per cent. The treatment of infected hemothorax should be early, simple pleurotomy with irreversible drainage being the best procedure to adopt. The mortality of cases operated on by the older methods is 32 per cent., that by pleurotomy and irreversible drainage is only 6.7 per cent. The total mortality from purulent pleurisy without operation is 24.3 per cent., and 37.5 per cent. when primary thoracotomy is done. Late removal of missiles is indicated in all cases where subjective or objective disturbances persist.

Transmission of Typhoid Fever in Hospitals.—Contagion of typhoid fever is always a matter of practical interest to medical men, and hospital contagion is not as uncommon as many would have it, as is proved by a recent experience at the Medical Clinic of the University of Geneva. A young woman was admitted to the Clinic with typhoid. She was in a very delirious state, so that it was quite difficult to carry out treatment properly, especially bathing, because not only did the patient struggle but also passed feces involuntarily. All the necessary conditions for direct contagion were consequently presented by the patient, and in spite of all the precautions taken by the personnel, ten days later two nurses came down with typhoid fever. A short time after this event another young woman with typhoid was admitted to the hospital. This patient also was not docile and in turn infected two night nurses. Such cases are unfortunate but may sometimes occur unless vaccination of the personnel is done.

But what is still more difficult to avoid is transmission from an unrecognized case of typhoid to other patients in the same ward. Last spring a woman, 48 years of age, was sent into the hospital with the diagnosis of gastroabdominal influenza. She complained especially of general fatigue, which she attributed to overwork on account of recent illness of one of her children. The absence of any rise of temperature and the indefinite gastric symptoms presented did not lead even to the suspicion of typhoid fever, until ten days after her entrance the temperature went up, and a seroagglutination reaction was positive. The patient was at once removed to the typhoid ward, but nevertheless she had had sufficient time to infect her two neighbors who had come to her bedside. The two patients were convalescing, one from a cardiac affection, the other from chlorosis. Another example of typhoid contagion was that of a young woman 26 years of age. Her child, 18 months old, whom *she had nursed up to that time*, was given to friends to be cared for while the mother was in hospital. The friends soon noticed that the infant had a slight diarrhea, which they thought was the result of weaning, but a fortnight after, the woman who took care of the child came down with typhoid, and shortly afterwards four other members of the family were taken ill with the disease, as well as a relative, eighty-six years old, who came in to help. The latter died in six days after the onset of the typhoid symptoms. Although the infant had only a mild diarrhea which did not affect its general health, a positive typhoid seroreaction was obtained and bacteriological examination of its stools revealed the typhoid bacillus.

Pathology of Malignant Tumors of the Anterior Mediastinum and Thymic Region.—Dr. Delessert, late assistant at the Clinic for Children's Diseases, has carried out some interesting researches on the pathology of malignant tumors of the anterior mediastinum and thymic region, which have not been published in the medical press. His material comprised six cases, and an interesting fact to be noted is that in none of them was it possible to discover the presence of characteristic elements of the thymus, such as Hassal's corpuscles, or cortical or medullary cells of the thymus, although long and repeated histological examinations were made. In all the six cases with the exception of one, an anatomical diagnosis of lymphosarcoma of the mediastinum could be made with certainty after a carefully controlled microscopic examination. The case making the exception was of a very special nature, as microscopically the presence of nerve cells and fibers was distinctly evident, so that the diagnosis of malignant ganglioneuroblastoma was made. Dr. Delessert is of the opinion that primary malignant growths of the anterior mediastinum and thymic region develop from the various tissues and organs contained in the mediastinum. The thymic origin of the majority of primary malignant growths of the anterior mediastinum is not usually evident, so that the term malignant neoplasms of the thymus should be reserved—at least until more information is obtained—for tumors of the mediastinum in which there is no doubt as to the presence of anatomical elements of unquestioned thymic origin.

6. The Diagnosis of Paralytic or Early Poliomyelitis. Samuel A. Levine.

1. Unusual Cure of Large Hemangioma.—Donald S. Adams reports the case of an infant five days old, one of twins, delivered by forceps, with a tumor of the right chest wall. The physician who delivered the child noticed the tumor at the time of birth. Inasmuch as it did not decrease in size he aspirated, getting several cubic centimeters of blood. The tumor became somewhat larger so it was thought best to have hospital care. Examination on admission to the hospital showed a hemangioma, rather malignant in appearance, attached to the mid-axillary line, by a sessile pedicle. Its measurements at the time were 17.5 cm. x 15 cm., and 35 cm. at its greatest circumference. After remaining stationary in size for some ten days the tumor increased in size, and the child's temperature slowly rose to 102° F. The temperature, of a septic type, continued for over two weeks, when it came down and the child's general condition seemed improved. The tumor appeared to be decreasing in size and in places had broken down and sloughed. From this time the tumor gradually contracted and discharged a moderate amount of bloody fluid. When the child was 2½ months old the tumor had gone, leaving only a reddish scar. The writer concludes that the cure was not spontaneous. The credit was due to the outside physician who introduced the exploring trocar and to the surgeon in charge of the case, who deemed it safer to wait and watch its progress before attempting anything radical. The rise in temperature, lasting from the last of December to the middle of January, is significant. At the end of this time the tumor began to decrease in size. Either there was secondary infection following the introduction of the trocar, or a thrombotic process was started, thus leading to the subsequent slough. It may have been a combination of the two. At any rate its disappearance was not unlike the results obtained in the use of Coley's serum, both locally and in the general reaction, as evidenced by the temperature.

4. The High-Grade Neurasthenic.—Herbert J. Hall says that William J. Mallory recently classified neurasthenics into six types: (1) Neurosis or anxiety neurosis; (2) mild, rare, or atypical psychosis, that is, manic depression, psychosis, and dementia precox; (3) incipient tuberculosis; (4) low grade cryptic infection; (6) cerebral arteriosclerosis. He believes the general practitioner into whose hands most of these cases fall will have a good deal of difficulty in fitting all of his "neurasthenic" patients into these classes. He sees many patients who are relatively normal physically and mentally, and yet they are tired, inefficient, nervous, irritable, sleepless, have rapid hearts, a high or low blood pressure, dyspepsia, and are depressed, worried, and apprehensive. A careful examination into the lives of such patients usually shows a surprising disregard of mental and physical hygiene. Having done all that can be done for these patients from the standpoint of habit modification, a valuable lesson may be learned from the orthopedist, who has drawn attention to the relationship between bodily mechanics and metabolism. It happens that a good many sufferers from flat-foot, sacroiliac strain, and backache belong also to the relatively normal or what may be called the high-grade neurasthenic class. The orthopedists discovered that they could not bring about permanent relief for backache and foot strain without rebalancing and rebuilding the entire body. Rebalancing the body in relaxed, slumped, flat-chested individuals, which most of these patients are, has involved taking up the abdominal slack by appropriate exercises, and submitting the patient to a general physical setting up. Very interesting results have followed such treatment. Not only have orthopedic difficulties been relieved, but functional disturbances, even those of very long standing, have frequently been disposed of. This same setting up process has yielded no less striking and encouraging results among the neurasthenic. The neurasthenic, plainly enough, needs exercise, but the orthopedists have realized that it is not muscular development which is needed first, but rest and overcorrection of faulty posture in bed. Weeks of treatment, with massage and careful feeding, may be required before results begin to appear, but persistence meets with due reward. Such treatment cannot be carried out offhand; one must learn the details from the orthopedist, as the job is often mechanically difficult. Only in a well-ordered sanatorium can such treatment be adequately and safely carried out.

2. Laryngeal Diphtheria.—John F. Hogan quotes statistics showing that in 1919 and 1920 there were 246 deaths in the city of Baltimore due to diphtheria of various types. Of this number 82.11 per cent. were laryngeal diphtheria. This fatality was in inverse proportion to the promptness with which the physician was called and antitoxin administered, and intubation was performed in only 50 per cent. of the fatal cases, and antitoxin given in only 83.74 per cent. The death rate in this type of diphtheria should be practically *nil*. A most erroneous belief that seems quite prevalent today is that diphtheria of the larynx cannot exist without clinical manifestations of diphtheria of the pharynx, postnares, or the nares. It should be remembered that in many cases of laryngeal diphtheria there is no pseudomembrane, and in some few not even a hyperemia of the pharynx. Yet the edema in the larynx may be quite sufficient to cause death by mechanical obstruction unless intubation is resorted to promptly. Once laryngeal edema develops to such an extent as to cause marked edema, antitoxin will not act quickly enough to overcome the necessity of intubation. It is obvious that the desired reduction in the death rate from diphtheria lies in earlier recognition and timely treatment with antitoxin and intubation.

5. Heart Disease in Children of School Age.—Robert H. Halsey. (See MEDICAL RECORD, June 25, 1921, xcix, 26, p. 1115.)

8. Medicolegal Application of Human Blood Grouping.—Reuben Ottenberg calls attention to the fact that although the inheritance, according to definite Mandelian principles, of group specific substances in human blood has been known for ten years, the application of this information to medicolegal questions has not yet been made. He refers to the literature on this subject and presents the results of a detailed analysis of the offspring resulting from unions of persons belonging to the various groups, showing that in certain instances the possible kind of offspring are sharply limited. The unions which he tabulates are instances in which under certain circumstances deductions of medicolegal value may be drawn. On the other hand all unions containing a member of group IV and

unions of II and III may give rise to offsprings of any of the four groups. If the child's blood is the correct group for the alleged parents, then we can say that the child *could* be their offspring, not that it of necessity must be. But, on the other hand, if the child's group is wrong for the two asserted parents, then one can say with absolute certainty that the child must have a parent other than one of those asserted. The commonest instance in which this kind of information could be applied, of course, is that of disputed paternity. Here one can readily tabulate the instances in which it is possible to be sure that the child is illegitimate, or is not the child of an asserted father. The same kind of evidence can be used to prove the illegitimacy of the offspring or to prove the innocence of a corespondent asserted to be the father of a given child. Likewise in cases of disputed maternity or substitution of one child for another it can be shown under certain findings that the child is spurious. In view of the importance of the questions often at issue, Ottenberg says it seems as though some legal means could be devised by which persons concerned be compelled to allow the examination at the hands of a representative of the court.

10. Endoscopic Removal of Sand Spurs from Larynx and Tracheobronchial Tree.—H. Marshall Taylor discusses a type of foreign body in the air passages which he finds has received very little attention, there being only sixteen cases of sand spur as a foreign body reported in the literature so far as he has been able to ascertain. In Florida, where the sand spur (*Cenchrus tribuloides*) is very abundant, he has collected sixty-nine cases, nineteen of which have come under his personal observation. The sand spur as a foreign body is seen most frequently in children. When the sand spur is aspirated the larynx is the most frequent point of lodgment. The sand spur has no inherent property. It should be placed in the category of a foreign body producing only mechanical effects. The method of its removal which has proved satisfactory in the writer's hands consists in putting the head in extension at the occiput resting on the table. This insures an extension of the occipito-atloid joint, and gives a satisfactory view of the anterior commisure, which has been the most frequent point of lodgment of the sand spur. In every case in this series the child or parent had made the correct diagnosis, giving the history of inspiring the foreign body, and citing the occurrence of laryngeal spasm. In reply to a questionnaire sent out the writer has learned of five fatalities in which the sand spur was the etiological factor, while one fatality occurred in the series of cases herein reported.

12. Observations of Hemorrhages of Ovarian and Tubal Origin.—Edward A. Schumann asserts that the recognition of other causes than ectopic gestation as a cause of hemorrhage into the abdominal cavity from an ovary or fallopian tube has been rather neglected, even though such other causes are known to exist. The preoperative differentiation from hemorrhage due to ectopic pregnancy is rarely possible. It is important, however, from the personal, as well as the medicolegal standpoint, that a diagnosis of ectopic pregnancy should not be made in cases in which pregnancy should not exist, until an embryo is found or evidences of decidual and placental formation are revealed by the microscope. Pathological studies show that when hemorrhage takes place from an ovary, there is usually, if not olways, to be found some disease of the ovarian blood vessels such as degenerative arteritis. Normal ovaries do not give rise to massive hemorrhage.

3. Notes on the Administration of Hydrochloric Acid.—J. Campbell McClure and Henry A. Ellis state that the address of Professor Haldane delivered in Edinburgh on March 4, on "Recent Advances in the Physiology of Respiration, Renal Secretions, and Circulation," has rendered it advisable to publish certain observations and deductions made in the course of another investigation. They feel, however, that in view of Professor Haldane's lecture confirming their observations of the extreme importance of the acidity of the urine in the regulation of the kidney system, that the importance of the estimation of the renal functions in this direction should be emphasized from a clinical point of view, while the material importance of estimating the blood pressure of all cases in which acid was being administered should be reported. So far, experience has taught the writers that dilute hydrochloric acid is not the—in acid sensitive cases, at least—harmless tonic the books would have one believe it to be, and they are sure that when acid is being administered the blood pressure should always be estimated from time to time, and the urine be tested occasionally for its acid and ammonia relations. They also feel that in cases in which an early condition of renal insufficiency is suspected, the "rest urine" should be compared with the "alkaline tide urine" in respect of their relative acidity. Their observations lead them to the following conclusions: (1) That acid largely regulates the amount and character of the urine excreted, by its action on the renal tissue. (2) That this is largely controlled by the increasing acidity of the blood (acidemia) tending to raise the blood pressure; otherwise the kidneys would not be able to maintain the necessary balance between acid and alkali. This regulation is so delicate that in health the normal variation of blood pressure is not apparent, other causes of increased blood pressure contributing to its concealment. (3) That when impairment takes place owing to the breakdown of the chemical balance, general acid sensitiveness occurs, and this condition is accompanied by a rise in blood pressure. If the structure of the renal cells is not injured this is not maintained unless the acidemia continues. If the structure of the cells is injured, the rise of the blood pressure is more or less permanent until other forms of compensation are established. When this structural alteration has occurred acid administration and acid feeding are contraindicated. Where acid is being administered in doubtful cases the blood pressure should always be observed, to avoid the danger of overdose. Overdose is also indicated by the "alkaline tide urine" approaching the "rest urine" in character. The writers have come to the opinion that the reason why, during treatment with acid, a rise in the blood pressure is reversible, that is, followed by a more or less similar fall, while this subsequent fall in blood pressure is not easily reversible, is because an acidosis may be transferred to the tissues, the acidemia thus being changed into a histo-acidosis, and this causes a fall in the blood pressure. If a histo-acidosis is established it is not easy to raise the blood pressure again, because of the difficulty of either raising the acid content of the blood above that of the tissues or of reducing the acidity of the tissues below that of the blood, the fluid pressure thus persisting toward the tissues, while the balance is against the blood.

4. The Action and Uses of Kaolin in the Treatment of Asiatic Cholera.—Ronald R. Walker points out that the kaolin treatment of cholera has been found to possess the following advantages: (1) Simplicity of method; (2) absence of relapse; (3) cessation of loss of fluid; (4) great improvement in the condition of the patient, the patient becoming rapidly free from a general "toxic condition"; (5) early return of the passage of urine; (6) early and rapid convalescence. He describes laboratory experimental work carried out to determine the method of action and the effects of kaolin, from which he draws the following general conclusions: The action of kaolin is twofold, mechanical and adsorptive. (1) *Mechanical*—The administration of such large quantities of kaolin as are used in the treatment of cholera almost fill the bowel, and the passage of this mass through the bowel must enclose and carry with it a very large number of bacilli. It has, however, no bactericidal effect, and this fact calls for energetic action in the destruction of feces in all cholera cases treated by this method. The fact that

the kaolin forms an adherent coating to the walls of the bowel points to its usefulness in ulcerative forms of colitis, though in these cases the rectal method of administration in the form of enemata and long-tube lavage would be preferable owing to the possibilities of errors of digestion arising, long after administration, due to the adsorptive properties of kaolin for ferments 2. *Adsorptive.*—This, the chief function of kaolin, is very marked. From the experiments reported it is clear that, at least in the case of cholera, and probably in diphtheria, ptomaine poisoning, bacillary diarrhea, and general toxic conditions, kaolin has a wide range of use. In cholera, the first result of its administration is the cessation of vomiting. This seems to be due to the adsorption of toxic bodies in the upper alimentary tract. This is followed by cessation of diarrhea and consequent loss of fluid which is caused by the presence in the bowel of irritant substances of a toxic nature. The presence of a layer of kaolin on the walls of the intestinal tract would appear to act partly as a filter-bed and prevent the transmission of toxins to the patient. The adsorptive action of kaolin does not appear to be chemical. Professor Bayliss has pointed out that kaolin is an electro-negative colloid, which sign may be changed by allowing it to adsorb ions of opposite sign to itself. This, the writer takes it, occurs in the small intestine. This electrical reaction may explain the marked difference in treatment of cases of cholera which have had saline injections preceding the kaolin treatment, to those treated only by kaolin.

Discussion on Visceral Syphilis, Especially of the Central Nervous System and Cardiovascular System.
1. Introductory Remarks. Thomas Beattie.
2. Opening Paper. Clifford Allbutt.
3. Clinical Observations. Ernest S. Reynolds.
4. Syphilis of the Heart. John Cowan and J. K. Rennie.
5. The Anemias of Syphilis. John Eason.
6. Syphilitic Aortitis. A. G. Gibson.

2. Visceral Syphilis, Especially of the Central Nervous System and Cardiovascular System.—Clifford Allbutt reviews the morbid anatomy of the syphilitic process and shows that it may be seen in little in the primary sore. Wherever it is found it consists in a lympharteritis with consequential irritative and atrophic effects. The visceral lesions are essentially similar and may be regarded essentially as a disseminated lympharteritis. The division of syphilis into time periods—as primary, secondary, tertiary, and visceral—is based upon superficial characters and is misleading. The pyrexial phase, slight as it may be, indicates a general syphilitic sepsis, in which the cerebrospinal system is soon involved. Early necropsies have shown that in the pyrexal phase the aorta, brain, liver, and other viscera become infected, and that the central nervous system does not long escape. In all diseases of the cord the cerebrospinal fluid should be examined soon after the onset of the pyrexial phase, and the cerebrospinal fluid tested from time to time parallel with the blood testing. The fact is emphasized that syphilis can evade intermittent and precarious treatment better than any other virus, hence the necessity for early, thorough, and systematic treatment.

4. Syphilis of the Heart.—John Cowan and J. K. Rennie record the fact that they have seen more than one example of syphilitic disease of the pulmonary artery in patients who died a short time after infection. The lesions are similar to those found in the aorta but much less common. They have also seen in a case of secondary syphilis a diffuse fibrosis of the muscle exactly comparable to that described by Warthin as occurring in the hearts of children who had died from congenital syphilis, in which he found spirochetes. The diagnosis of syphilitic disease of the heart is by no means easy, and in fact any disease of the heart may be due to syphilis. In an endeavor to ascertain the incidence of syphilis in a series of 104 patients who were suffering from disease of the aortic valves it was found that 32 (30.7 per cent.) gave a definite history of antecedent syphilis, or showed a positive Wassermann reaction or other evidence of syphilis. Of these patients 33.6 per cent. had suffered from acute rheumatic fever, and in the remaining 34.5 per cent. of patients the nature of the valvular lesion was undetermined. It seems probable that the incidence of syphilis is greater than that shown, a conclusion that is emphasized by the fact that a corresponding series of cases of aortic aneurysm, 19 in number, showed a syphilitic origin in 63.1 per cent. The figures in a corresponding series of cases of mitral valvular disease show a very different picture, only 0.8 per cent. having suffered from syphilis. The combination of aortic and mitral disease, particularly in the twenties, strongly suggests a rheumatic cause, while the occurrence of purely aortic disease after 35, and the absence of a clear history of rheumatic fever, strongly suggests a syphilitic origin. There does not seem to be any close connection between syphilis and other forms of cardiac disease, such as auricular fibrillation, heart block, and myocardial disease. In the treatment of cardiac syphilis the two sides of the question—the cardiac side and the syphilitic side—must be borne in mind. In the cases due to syphilitic disease specific treatment is as urgently required as in other syphilitic diseases. Too much, however, must not be expected from such medication, since the lesions are as a rule in an advanced stage when recognized. It is advisable to refrain from heavy drugging with kharsivan and the like, using only moderate doses. The best results will, of course, be attained if the disease is recognized at the outset, before gross cardiac failure has ensued, and the appropriate treatment instituted at that stage.

5. The Anemias of Syphilis.—John Eason states that in addition to the features mentioned as characterizing the anemia of secondary syphilis by the usual authorities, a number of cases have come under his observation which have shown a much more severe degree of oligocythemia and also of poikilocytosis, aniscytosis polychromasia, and punctate basophilia. There were normoblasts and megaloblasts. Eosinophile and neutrophile myelocytes were found sometimes in fair numbers in one case. The color index was definitely above 1 in all cases. The anemia was grave with about 1,000,000 red cells, and about 20 per cent hemoglobin. Enlargement of the spleen was a feature sooner or later in all cases. In the cases that died there was bone marrow reaction but no hemosiderin reaction of the liver. An attempt to demonstrate the spirochete failed in bone marrow and also in spleen; nevertheless it was practically certain that syphilis was the causal factor in these cases. Anemia with chronic splenomegaly is a condition which may occur in the tertiary stage of acquired syphilis. The last stage of the untreated condition is contracted cirrhosis of the liver, ascites, and melena. Throughout the whole tertiary period the sole clinical difference from Banti's disease as described by him may be the history or demonstration of syphilis, and possibly of abdominal pain and tenderness. In the spleen excised during the tertiary period spirochetes are found. In view of the fact that splenectomy is the only treatment which stays or prevents the otherwise fatal issue of Banti's disease, it is necessary to learn whether this form of treatment should be recommended in the syphilitic form. So far as can be stated at present Eason believes that the recommendation to operate cannot be based on quite the same grounds. It is not known whether the syphilitic cases run the comparatively brief and fatal course of Banti's disease or pernicious anemia. Moreover, some of them do make a partial response to antisyphilitic treatment. Of six collected cases and one of his own treated in this way the Wassermann test became negative in one only. In one the general condition became less satisfactory; in two no benefit was derived, while in three some improvement occurred. In the few cases in which operation has been done the early result has uniformly been improvement after the operation. In the management of these cases, the writer has had no untoward result from thorough antisyphilitic treatment controlled after each injection of salvarsan by a complete blood examination.

1. The Leucocyte Picture in Influenza.—C. H. Bunting, after reviewing the recent literature on this subject, says it may be summarized by stating that in influenza there is an early inhibition (not exhaustion) of the marrow activity by the infecting agent, resulting in a leucopenia which is characteristic of the disease. The marrow is capable of stimulation upon pyogenic infection as a complication, and there results a leucocytosis usually of moderate degree. He has made a study of the leucocyte picture in ten cases of primary infection, cases being selected which showed no signs of deep respiratory infection on admission. The consistency of the blood findings in these cases seem to justify certain conclusions when taken in conjunction with the work of others. They show that uncomplicated influenza has a characteristic blood picture the features of which are an early neutrophile leucocytosis, followed by a sharp drop to a leucopenia, with a marked deficiency of cells of marrow origin and of blood platelets and with a lymphocytosis of varying degree. There is a gradual return toward a normal picture, but a cessation of fever and of symptoms may occur with the presence of a very abnormal blood count. The leucopenia suggests somewhat that of typhoid fever and also somewhat that of measles. It indicates sharply that the infecting organism is not a pyogenic coccus. What the nature of the marrow inhibition or chemotaxis may be is not evident. The great poverty in circulating neutrophilic leucocytes would seem to account for the frequency of pyogenic complications in influenza. These complications in two of the cases observed have followed directly upon a very low neutrophile blood content. There would seem to be a danger limit of neutrophile reduction beyond which we become a prey to coccus infection. This is the basis for the point that in practice influenza patients should not be allowed to get up and resume their ordinary life immediately upon the cessation of fever, but should be kept quiet and isolated until their blood has approached at least the normal leucocyte formula, which apparently requires almost a week from the cessation of fever. The great platelet decrease in the blood in influenza is apparently responsible for the hemorrhagic character of the pneumonic exudate in that complication of the disease. In view of the blood changes there arises an interesting theoretical question as to the nature of the cellular defense (if such there be) against the invading virus.

4. The Relation of the Endocrine System to the Glycemic Reaction following the Injection of Homologous Protein.—G. L. Rohdenburg and O. Krehbiel have observed the variations in the blood-sugar content of normal rats and mice injected with homologous and heterologous protein. With the intention of investigating the hypothesis that the occurrence of tumors is due to some endocrine disturbance, they have also studied the effect of ablation of one or more glands of internal secretion upon the glycemic reaction following the injection of homologous protein. As a result of the experiments they record it appears that the glycemic reaction, which follows the injection of homologous protein, is under the control of the endocrine system and that inhibition of the reaction may be viewed as a disturbance of metabolism due either to hypoactivity or hyperactivity of the endocrines. Whether this disturbance of metabolism is or is not of etiologic significance in neoplasia cannot be stated from the facts available at the present time.

8. An Evaluation of the Allen Treatment of Diabetes Mellitus.—John R. Williams presents a study of 100 patients who had reducing substance in the urine from which he concludes as follows: (1) Statistics as to the prevalence of diabetes, cures obtained and other data, based on former and inaccurate and incomplete methods of study, are untrustworthy. It is quite impossible therefore to compare with fairness results obtained by the use of the Allen method and results obtained by methods formerly in use. (2) In spite of these difficulties an extended clinical experience covering the use of all known forms of diabetes treatment justifies the conclusion that the Allen treatment is a distinct clinical advance. While permanent clinical cures are not attained, nevertheless patients for a considerable time are much benefited. (3) It is difficult to say how much is added to the expectancy of life of the diabetic by this treatment. In young people in whom the disease is most serious it would appear that it is at least doubled. Middle-aged and elderly diabetics who are not too seriously afflicted with complications and when faithful to the treatment can probably survive the life expectancy of the average normal individual. (4) The Allen method is of the greatest service when instituted early in the disease. Most of the failures in its use are due either to serious complicating disease, or more frequently to unfaithfulness on the part of the patient. In the majority of patients its value is in inverse proportion to the seriousness of the failure of metabolism.

10. Some Observations on the Use of Arsphenamin: Its Effect on the Kidneys and Its Therapeutic Results.—Horace B. Anderson has carried out kidney functional tests on 39 cases after they have received thirty doses of arsphenamin, each dose consisting of 4.6 decigrams and distributed over a two-year period. These tests failed to give any evidence of injury to the kidneys. He emphasizes that the efficiency of any method of treatment must ultimately be determined by the Wassermann reaction. It is more trustworthy to use at least two antigens; the acetone soluble antigen is a safe guide to diagnosis and the alcoholic extract reinforced by cholesterin is an excellent guide to treatment. It is impossible to say how much arsphenamin and how many courses of mercury may be necessary to produce a negative Wassermann reaction in any given case. Six injections of arsphenamin and one course of mercury, the amount too often prescribed by certain groups of physicians, may produce one negative Wassermann reaction, but the average case of secondary or tertiary syphilis will require twelve or more doses of arsphenamin and a corresponding amount of treatment with mercury to produce a negative Wassermann reaction, and one which only with further treatment may reasonably be expected to persist.

La Presse Médicale.

July 9, 1921, xxix, 55.

Treatment of Gonorrheal Epididymitis with Plasmotherapy.—Weill means by plasmotherapy autoserotherapy in which the effusion from the inflammatory lesion is reinjected into the patient. The treatment cannot be used in routine as not enough liquid could be procured in the ordinary case. In three of his patients, however, the effusion amounted to a hydrocele, and the author could inject as high as 30 c.c. in one of the three. The operative technic is of the simplest, for it is only necessary to puncture and aspirate, warm the punctate for a moment at a temperature of 45° C., and then inject under the skin of the thigh, outer aspect. The reason for heating is merely that the said temperature is sufficient to destroy any of the gonococci, should they have gained access to the liquor. In summing up his cases the author states that the usual duration of epididymitis was abridged considerably by the treatment; that the rapidity of cure bore a direct relation to the amount injected, and that the injection was attended by no reaction, whether local or general. Finally the punctate if injected into subjects other than the original patient appears to possess the same efficacy.

Book Reviews.

MICROBIOLOGY. A Text-book of Microorganisms General and Applied. Edited by CHARLES E. MARSHALL, Amherst, Mass., Professor of Microbiology and Director of Graduate School Massachusetts Agricultural College. Third Edition, Revised and Enlarged, with 200 Illustrations. Price, $4.00. Philadelphia: P. Blakiston's Son & Co., 1921.

FOR the benefit of those who are not familiar with this admirable work we may explain that it is a treatise of 1070 pages, containing contributions by twenty-five experts in the various departments of microbiology. The work is divided into three parts, covering, respectively, the Morphology and Culture of Microorganisms, the Physiology of Microorganisms, and Applied Microbiology. Under the latter head are ten divisions dealing with the Microbiology of Air, of Water and Sewage, of Soil, of Milk and Milk Products, of Foods, of Alcoholic Fermentation and Derived Products, of Special Industries, of the Diseases of Man and the Domestic Animals, of the Microbial Diseases of Insects, and the Microbial Diseases of Plants. A brief history of the origin and growth of the science of microbiology forms the opening chapter. The book is well illustrated with 200 pictures in the text and a colored plate of the malarial parasites. We know of no work of recent date that can be compared to this in the amount and authoritativeness of the information therein contained, and can heartily commend it to all seeking knowledge on the subject of microbiology.

THE NEW POCKET FORMULARY. With an Appendix Containing Formulæ and Doses for Hypodermic Medication; Posological Table; Obstetrical Table; Table of Apothecaries' and Metric System of Weights and Measures; Fractures, Dislocations and Sprains; Ligations of Arteries; Hemorrhages and Wounds; Treatment of Asphyxia and Apnea; Poisons and Antibodies; Incompatibilities and Baths; Miscellaneous Emergencies; Tables of Differential Diagnoses, Eruptive Fevers, Diet Lists for Various Diseases, Materials and Drugs Used in Antiseptic Surgery; Formulæ for Fluid Foods, etc. By WILLIAM EDWARD FITCH, M.D., Late Major Medical Reserve Corps, U. S. A., Formerly Lecturer on Surgery, Fordham University School of Medicine; Assistant Attending Gynecologist Presbyterian Hospital Dispensary; Attending Physician to the Vanderbilt Clinic, College of Physicians and Surgeons, New York City; Member of the American Medical Editors' Association, Member of the Medical Association of the Greater City of New York, etc. Third Edition, Revised. Price, $2.50. Philadelphia: F. A. Davis Company, 1921.

WE are not partial to ready made formulæ, being of the opinion that the practitioner who writes his own prescriptions to meet the indications present in the individual case will be more successful in overcoming disease. Yet almost every physician has some "favorite prescriptions" upon which he has learned to rely in the average case, and we may learn something in studying these remedies which others have found useful. Dr. Fitch has collected a large number of these in his little book and has been very wise and conservative in his selection.

STUDIES IN DEFICIENCY DISEASE. By ROBERT MCGARRISON, M.D., D.Sc., Hon. LL.D. (Belf.), Fellow of the Royal College of Physicians, London; Lauréat de l'Académie de Médecine, Paris; Honorary Surgeon to the Viceroy of India; Lieutenant-Colonel, Indian Medical Service. New York: The Oxford University Press, American Branch.

THIS is an interesting and authoritative treatise on one of the most live subjects in medicine today. Even yet we know but little of the composition of vitamines, but Dr. McGarrison has given us a capital definition of the action of these vital substances. "Vitamines," he says, "are as a spark which ignites the fuel mixture of a petrol-driven engine, liberating its energy. The spark is of no use without the fuel, nor the fuel without the spark—nay, more, the efficiency of the spark is dependent in great measure on the composition of the fuel mixture."

The work is divided into four parts, treating respectively of: (1) the nature of vitamines and a description of the experimental study of them; (2) the symptoms of deficiency diseases and the factors influencing the onset of deficiency diseases; (3) the pathogenesis of deficiency diseases; (4) the practical prophylactic and therapeutic application of the knowledge gained by the studies and experiments previously described. The author discusses many interesting points, such as the influence of race, age, and sex, fatigue, faulty hygiene, mental depression, and infectious diseases in modifying the results of a lack of one or another of the already known vitamines.

THE AMERICAN YEAR-BOOK OF ANESTHESIA AND ANALGESIA. 1917-1918. F. H. MCMECHAN, A.M., M.D., Editor. New York: Surgery Publishing Co., 1921.

THE present volume, which is the second of its series, has been delayed by the exigencies and demands of the World War. It comprises about 500 double column pages. The number of separate articles is 87, and the number of individual contributors is as large, for while a few authors cover more than one subject, two or more collaborate in certain articles. The contributors are made up of specialist anesthetists, specialists in various branches of operative surgery, pharmacologists, military men, dentists, etc. An analysis of a work like this is impossible within a small compass. It will no doubt be indispensable to all operating surgeons, obstetricians and dentists, and professed anesthetists. The total omission of any allusion to twilight sleep under "anesthesia in obstetrics" or elsewhere may be regarded as significant.

LE SYMPATHIQUE ET LES SYSTÈMES ASSOCIÉS. Par A. C. GUILLAUME. 2me edition refondue et augmentée. Paris: Masson et cie., 1921.

THE first edition of this volume of nearly 400 pages appeared in 1919. The subtitle is "Clinical Anatomy, Semeiology and General Pathology of the Neuroglandular System of Organo-Vegetative Life." There is a special preface contributed by Professor Pierre Marie, the distinguished neurologist. Among the novel sections is one on the elective pharmacology of the organo-vegetative system, in which the response to drug activities is discussed, which naturally shades into sympathicotonus, para-sympathicotonus, and neurotonus. The entire subject of internal secretions is covered as one of the systems associated with the sympathetic. One has only to compare this volume with the old monograph on the same subject by E. Long Fox, published some thirty-odd years ago, to visualize the radical character of the evolution of our knowledge of the sympathetic nervous system and its influence on the phenomena of disease.

A PHYSICAL INTERPRETATION OF SHOCK, EXHAUSTION and RESTORATION, an Extension of the Kinetic Theory. By GEORGE W. CRILE, M.D., Senior-Consultant in Surgical Research, A.E.F., 1917-1918; Professor of Surgery, School of Medicine Western Reserve University; Visiting Surgeon to the Lakeside Hospital, Cleveland, Ohio, U.S.A. Edited by AMY F. ROWLAND, B.S., Lond.: Oxford University Press. New York: American Branch, 1921.

IN this volume Dr. Crile reviews his previous work on the production of fatigue, shock, and exhaustion in the light of new facts and observations derived from his war experience. Those familiar with the author's kinetic theory of shock will here find it elaborated and strengthened with much new material, both clinical and experimental. This theory has been put to the crucial therapeutic test at the Lakeside Clinic, Cleveland, and by its practical application the mortality rate for bad surgical risks has been materially lessened and the range of operability extended. The operative mortality of capital abdominal operations has been reduced to 1.2 per cent., and that of thyroidectomies to 0.88 per cent. "With such evidence of the practical value of biophysical methods of attack upon clinical problems," Dr. Crile says, "it would seem that with the extension of physicochemical investigations, medicine may approach a place among the exact physical sciences, and the physician may attack his problem from the more secure standpoint of the physicist."

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Twenty-second Annual Meeting Held in Washington, D. C., June 3 and 4, 1921.

(*Concluded from page* 388.)

A Therapeutic Report.—Dr. JOHN BLAKE WHITE of New York presented this communication.

The Teaching of Medicine and Therapeutics to Undergraduate Students.—Dr. THOMAS F. REILLY of New York read this paper. (See page 447.)

The Aim of Modern Therapeutics.—Dr. L. RADCLIFFE GROTE of the University of Halle presented this paper by invitation; it was read by Dr. JOHN C. HEMMETER. (See page 449.)

Some Remarks on the Cause of Therapeutic Nihilism.—Dr. FRANCIS M. POTTENGER of Monrovia, Cal., presented this communication. (See page 451.)

Dr. OLIVER T. OSBORNE of New Haven expressed his hearty indorsement of the papers by Drs. Reilly and Pottenger and hoped that what had been said would sink into the minds of all.

Dr. JAMES M. ANDERS of Philadelphia said he was in entire agreement with the positions taken by Dr. Reilly and Dr. Pottenger. As Dr. Reilly had said, we had been swinging away from solely didactic instruction toward clinical teaching until the former was too much neglected, and the reason we should turn the pendulum in the reverse direction, for some distance at least, was that there were so many opportunities at the present day for the student to get practical training after leaving school. He himself wished to emphasize the fact that too much stress was being laid upon the specialties in the undergraduate years of study. We had standardized undergraduate teaching and had begun to standardize graduate teaching, and one could foresee the time when much of the training now given to the undergraduate would be transferred to the graduate curriculum. Indeed, this tendency had already been established, and it was to be hoped that it would be carried further along, so that the past tendency toward over-specialization would be corrected. Dr. Pottenger had stated the situation correctly when he said that too much consideration was given to the disease and too little to the patient himself. In the speaker's own work as a consultant he rarely found physicians suggesting for overwrought nervous systems and mental worry repose, calmness, and optimism, things that invigorate rather than depress vital function, that increase rather than decrease resistance to disease. Medical schools had not been training the student to recognize the potent influence of the mind upon the body, and for the reasons stated by Dr. Pottenger little or no attention had been given in the past to the socalled applied psychology which would enable the student, when he went into practice, to meet successfully the almost universally pessimistic attitude of patients There was no doubt that at the present day we were burdened with too many specialties, yet he was impelled to suggest another—namely, "pessimism," with the view of bringing about the cultivation of a cheerful optimism. It was because of a defective education that physicians too often failed to instill optimism into their patients, which was often the best tonic that could be prescribed He had been glad to hear it urged that physiology should not only be taught to the undergraduates but also by the physician to his patients. For a number of years he had been trying to instruct his own patients in personal hygiene, and he was quite willing to add physiology. Physicians should teach not only their patients but the community in which they live all the hygiene and all the physiology possible as one of the best remedies for all the drugless cults to which the public was rushing like mad. The point which he wished to emphasize was that in the undergraduate school the student should be taught to establish and maintain a system of instruction in personal hygiene and physiology to his patients and the public. In his opinion, the society had a very distinct function to perform with regard to the education and training of men in therapeutics; it was time the members should carefully study their job and recognize that it carried with it great opportunities and grave responsibilities. The society should serve as a guide to the profession in all matters pertaining to therapeutics and so counteract the influence of the various drugless cults and pathies—each with a little virtue behind it—now so numerous and so popular that they actually cared for one-third of the population of the United States. The state should be made to recognize the fact that certain fundamental branches, *e. g.* anatomy, physiology, chemistry, and pathology, were necessary, no matter what practical system of the healing art the individual student wished to pursue in the future. It should be quite possible to combine the institutional interests, so far as the instruction of medical students in these basic scientific branches is concerned, and thus in one sweep speedily do away with the various cults. This society should be able to bring about the teaching of therapeutics and of the management of disease in general in our medical schools in a manner so broad and full as to leave little room for the pathies and drugless cults.

Dr. LOUIS F. BISHOP of New York said that a great change had taken place in the profession. In the old school all were taught that disease consisted of pathological anatomy and certain anatomical lesions. That school had more or less passed away and was being replaced by pathologic physiology—that the changes in pathological anatomy were the end result of disturbances in the physiology. That was very hopeful. In his own particular subject of the heart this tendency was very strong. Nothing had done more to abolish therapeutic nihilism than the technical observance of the disturbed heart and the possibility of recording the disorder as it appeared, and then applying the proper treatment. Probably the study of fibrillation had done more to destroy therapeutic nihilism than anything else in the last fifty years, for that so definitely showed the effect of a drug on a disordered condition. With regard to the psychological management of patients, he had adopted the plan of absolute frankness with every patient he came in contact with. Hardly a day passed that some doctor or relative of a patient did not say to him: "If you find anything definite, please don't tell the patient." He would reply that if they wanted anything concealed they must take the patient to someone else. He had found that by a policy of complete frankness he could get the cooperation of the patient. He would always say: "I hope and believe that you will improve under treatment." If one asked: "Am I liable to sudden death?" he would reply: "Yes." It was a curious fact that many hundreds of persons had accepted the fact, discounted it, and had forgotten it—had stopped worrying about it. It was very like life insurance; everyone knew he was subject to death, but he did not believe that it was going to happen to him, and so would not insure. By absolute frankness one could get the cooperation of the patient. If he was told you knew he was in danger, but hoped and believed he would get better, the fear would be discounted. In regard to educating people in regard to physiology and disease, Dr. Bishop said that for thirty-five years he had been active in the Society for Instruction in First Aid to the Injured, but every time he had tried to write some public article he had gotten it in the neck from the profession for trying to advertise his own practice. That was not fair. It was the duty of the profession as far as possible to instruct the public in such matters, and there ought to be some way in which such work could be censored before it got to the public so that that reproach could be avoided. The *Journal of the A. M. A.*, in criticising his last book, said that it was very fine work, but it meant that Dr. Bishop wanted the people to go to him. The American Medical Association was perfectly willing that anyone whom it might designate should take part in public health education, but if anyone else did it, it was self-advertising. It was difficult to examine into a man's motives, but that was no reason why every effort should not be made to disseminate true medical information as far as possible. Everyone in the community should be taught first aid to the injured and the first principles of pathological physiology and prevention of disease.

Dr. CHARLES E. DE M. SAJOUS said that in expressing his admiration for the papers presented by Drs. Keilly and Pottenger he wished to recall that therapeutics was being neglected to a material degree in our medical schools because it was still empirical and unscientific, even though pharmacologists contributed much to our knowledge. In his presidential address last year he had urged the fact, now conclusively established, that many drugs, the iodides and strychnine, for instance, produced their beneficial effects by stimulating certain ductless glands, and that it was through these glands that the curative power of several of our best remedies was exercised. This therapeutic method (see MEDICAL RECORD, Sept. 18, 1920), which Doctor Sajous had termed "pharmacoendocrine therapy," was of capital importance to the practitioner—sufficiently so, in fact, to have caused the London *Lancet* to recommend the study of endocrinology in this connection by the new chair of pharmacology to be founded at St. Mary's Hospital Medical School of London. The University of Pennsylvania had, however, taken the lead in this respect, its Graduate Medical School, at the request of our fellow member, Prof. James M. Anders, and its Medical Faculty, having created a chair of Applied Endocrinology, the first, by the way, in the history of medicine, to which the speaker deemed it a great honor to have been appointed.

Dr. SPENCER L. DAWES of New York said that for many years he, like Dr. Osborne, had been "a voice crying in the wilderness" in regard to teaching therapeutics and physiology. It seemed to him that the main point had been lost sight of. The fact was it was not taught, and he defied anyone to point out more than one out of ten schools that was teaching any therapeutics. They did not teach it. As he had himself said in a paper read at Atlantic City, they taught two things—to make a diagnosis and to make an autopsy to prove the diagnosis, and if they could teach only one thing, they taught them to make the autopsy. They did not care whether they cured disease or relieved the patient. It was well to know pathology and diagnosis, and how to look through a microscope, but the physician ought to know how to help the patient. Until we went back to first principles and taught therapeutics we would not accomplish what we were after. If one went to the medical schools today and asked the student what he was interested in, he would not find one in a thousand interested in the cure of disease, but only in surgery, otology, laryngology, etc. Dr. Dawes said he had taught in the medical schools for twenty years, and there was not one that taught therapeutics as it should be taught. Until we got back to teaching therapeutics, nothing would be accomplished. Another point was valuable. You might have your full-time man, but when you put in your whole lot of full-time men in the medical schools you would be losing sight of the man's personality, of the man who approached disease at the bedside and told the student how to treat disease—not as in the hospital, where directions were written and the nurse was told how to treat disease. The nurse would see that it was done. But how about the physician when he visited a private patient and told him to take something, and the patient would say: "I don't want to take that"; what would he do then? He would substitute something else. The student would not get that knowledge in the hospital, and would not get it until he was taught how to treat disease.

Dr. JACOB DINER said that no more proper subject could be brought before the society than the matter of therapeutics and the teaching thereof. Dr. Dawes found fault that there was no therapeutics taught in the schools. Dr. Diner said he would agree to that and more than that, that whatever therapeutics was taught was taught on a false basis. The main thing was to cover the text-book with every drug mentioned. He had seen valuable time wasted by teachers on some drug that experienced men had never heard of, simply because the literature somewhere mentioned that drug. One thing was rarely taken into consideration, the drug known as common sense and its application to the treatment of disease. That was a question often lost sight of. Another error often found in the teaching of the subject was absolutism of teaching and giving the student formulas which were "sure cures" for this, that, and the other thing. That reminded him of a story of a very good and careful observer who took detailed bedside notes of his patients. He had a case which presented a certain symptom-complex, and from day to day he watched the case and put down the remedial agents employed and what else he did for the patient. The patient did not get better; and finally one day, when calling, the patient's wife said to the doctor: "What do you think August asked for today? He wants pig's knuckles, sauerkraut, and beer." And the doctor said: "Let's make his last days happy and give it to him." The next day he called on the patient, expecting to find crape on the door, but August was sitting up, smoking, reading the paper, and enjoying life as much as ever; and the doctor put down in his notebook beneath the carefully recorded bedside notes: "Pig's knuckles, sauerkraut, and beer, sure cure." A short time after, Pat was taken sick, and the doctor prescribed pig's knuckles, sauerkraut, and beer, telling Bridget that this was bound to cure Pat. But the next morning Pat was dead—and the doctor added to his previous notes, after the words sure cure, "for the Germans, but it's hell on the Irish."

Dr. WILLIAM FITCH CHENEY of San Francisco expressed his agreement with what Dr. Reilly had said in regard to the swinging of the pendulum toward more therapeutic instruction. He had been through that experience himself. The teaching of former years was almost entirely didactic; now it was almost entirely clinical, but the students of today were not so thoroughly conversant with the cure of patients and disease as those of former days. He believed in compromise; they should have both. He was also in agreement with what Dr. Pottenger had said. It did not matter how much the physician knew of diagnosis, pathology, materia medica, the doses and qualities of drugs, his success as a practitioner came down to a question of personality; the man who knew it all might be a dismal failure, and the other a great success. The man with underlying optimism, who was ready to give his patients encouragement, would attain a success which the man who treated his patients overmuch with drugs would never reach. There were two classes of patients—those who had no serious illness and who would get well, and those who could not be cured. We could do an immense amount of good to patients who were not seriously ill; they were inclined to think they were very much worse than they really were; as Mark Twain said, one-fifth is real and the other four-fifths what he thinks. If you were convinced that the patient was not seriously ill, you could take away that four-fifths by reassurance and sympathy and common sense. Those in the other group, who had serious illness that could not be cured with drugs—but might be made worse—could also be helped by common sense and telling them the truth. Death was not the worst that could happen to a man; it was often a relief to one who was suffering, but he could be greatly helped by the exercise of common sense and reassurance, making him feel that the very best possible was being done to make him comfortable and prolong life. Dr. Cheney said he knew from observation that the brilliant student was not always the best prepared for practice, but that was one reason why men who were not well prepared were able to do for the patient what the well-prepared scientific man did not always do.

Dr. WILLIAM F. MILROY of Omaha expressed his commendation of the two papers. He had heard this theme developed to the same extent in an experience meeting. He had taught for thirty-five years, and was delighted to hear this discussion; for quite a long time he had felt almost afraid to suggest anything along this line in the society meetings. One was apt to be counted an old fogey, a "has-been" if he harked back to the methods he had found successful; but it was the duty of the society to promulgate authoritatively the views expressed in these papers and the discussion. He had been convinced that medical education was a lamentable failure in a large degree, owing to this devotion to the specialties and to the excessive stressing of laboratory work at the expense of the practical we had been taught and had found successful.

Dr. REILLY said that he and Dr. Pottenger felt

that they had been sitting for the time being in the criminal dock, but, because of the general approbation expressed by so many teachers of medicine, they were very glad, indeed, that they had been discharged as not guilty.

Dr. POTTENGER said he wished to emphasize the importance of maintaining the psychical as well as the physical side of the patient. It was noted in practice, but not in teaching. Nothing would do more for a chronic invalid than hope. He then cited the case of a doctor who developed tuberculosis and consulted two or three of the best physicians in a large eastern city, who made a diagnosis and told him to go west, which he did; but gave him no hope for recovery. One year later he came to Dr. Pottenger, who examined him and at once told him that he could be restored to health. This doctor then said to him: "That is the first word of hope I have heard for a year." He said that he was giving up his profession, for he would not belong to a profession that could give no hope. The man who neglected that factor was neglecting one of the biggest factors in cure. He himself would rather treat a patient with hope in a closed room than with discouragement in the open air.

Group Medicine.—Dr. GEORGE REESE SATTERLEE of New York presented this paper which dealt with the subject of group medicine in relation to focal infection. He stated that focal infections entered into every branch of medicine, either as etiological or contributory factors in disease. Certain well known diseases were generally recognized as originating in focal infections, mainly syphilis, tuberculosis, erysipelas, protozoal and parasitic infections. There was a large class of less well recognized focal infections caused by the streptococci in their various strains, and also the colon bacilli, which were not yet universally accepted. If one visited a general hospital in a critical way he would find, as the writer had in his own wards in the Fordham Hospital, from 60 to 80 per cent. of the patients showing evident focal infection, principally in the teeth and tonsils. Infected adenoids were quite frequent, and less frequent foci were otitis media, sinusitis, infected prostate and seminal vesicles, stricture of the urethra, and infections of the rectum. In the New Jersey State Hospital infected cervices had been enucleated with good results. It had also been shown that there were a certain number of streptococcic infections of the seminal vesicles which played an important rôle in some cases. The all-important thing was to remove all the foci of infection when that was possible. It could readily be seen from the large amount of work that was necessary in the removal of these focal conditions that cooperation among the internists, surgeons, and specialists was essential. This work could be accomplished in hospitals but it was an extremely difficult thing in private practice without a selective body of physicians, which he had chosen to call "group medicine." Group medicine was the only solution and some day we might see in our hospitals a focal infection ward, with a separate laboratory. It could easily be demonstrated that this sort of work in the hospital was an economical problem as well as a humanitarian one. The essentials of group medicine were as follows: 1. An *internist* who made a provisional diagnosis and outlined the essential examinations. He should follow up the patient before and after operation and take the responsibility. 2. A *surgeon* who had a deep appreciation of the medical needs of the patient as well as operative skill. Both physician and surgeon should be expert in interpreting radiographs, and have a working knowledge of other specialties. 3. A *nose and throat surgeon*, who was in sympathy with the work. 4. A *dental surgeon*, with a similar attitude. 5. A *radiographer*, who studied the patient from the viewpoint of both morphology and function. 6. A *general laboratory*. 7. A *special bacteriologist*, for research work and classification of bacteria. (This was a very important field if we were to make any advancement.) 8. A *technician*, for gastric contents and other secretions. The same person, preferably a woman, could have charge of special therapy, vaccines, etc. 9. A *follow-up system*, with nurse or clerk in charge, who could also do social service work, history taking, etc. 10. A *dental hygienist*, especially for hospitals, where private dentists were not practical, and the work was extensive. 11. *Special consultants*. 12. *Hydrotherapy and massage*. No diagnosis of metabolic disturbance exclusively should be made before focal infections were ruled out. The same might be said of the endocrines. Borderline abdominal cases were often relieved through the removal of foci of infection and many a postoperative failure had thus been turned into success.

The Future of Therapeutics.—Dr. REYNOLD WEBB WILCOX of New York presented this communication. (See page 453.)

Cardiological and Sociological Experiments in the Treatment of Heart Disease.—Dr. LOUIS FAUGERES BISHOP of New York described this experiment, which was conducted at the Good Samaritan Dispensary in New York. He stated that the cardiological end of the experiment consisted in giving to all those who might apply an examination involving a careful record of subjective symptoms, a general physical examination, a fluoroscopic examination of the heart, and orthodiagrams by the *x*-ray method, an electrocardiogram, a polygram with the Mackenzie polygraph, a Wassermann test, a blood examination, and uranalysis. The sociological innovation consisted in making those who enjoyed the benefits of the examination pay for the cost of the service. The equipment cost $5,000, and a charge of $37.50 was determined upon as necessary to cover the running expenses of the clinic, and, if the clinic proved a success, to pay for the equipment. Observations made in this clinic had revealed important and unsuspected facts in people who had previously been under observation for a long time, the most notable being in cases of cardiac discomfort of long standing. These had sometimes proved to be due to specific infection or a bundle branch lesion in people who had been told frequently that their trouble was indigestion. One man, notably, with a bundle branch lesion, had been under treatment in a hospital for many weeks for gastric ulcer. Many practitioners who had had no experience with the complete cardiological examination still believed that it was too expensive and troublesome to be applied in general practice. It was felt that if the service were given for nothing it would be utterly impossible to judge whether the profession or the public put any value on it or not. He felt that it would be an economic crime to give this service to all comers without charge. In addition to providing a complete cardiological service it was intended to make the clinic a place for the productive study of heart and tension conditions. It was decided in the beginning that the cases would be studied *seriatim* because the problems of cardiology which were most important were those which pertained to the average sufferer and not to the extraordinary or socalled interesting cases. Many persons came to the clinic because they felt that something was wrong with the heart and wished the matter confirmed by a definite investigation. A brief report of the first ten cases studied at the clinic was presented from which the writer thought certain conclusions could be drawn as to the character of the work that a clinic of this kind would be called upon to do. The first observation was that these patients all suffered from discomfort referred to the region of the heart. As was well known most heart trouble was without any such discomfort. This raised the question whether persistent discomfort referred to the region of the heart justified the diagnosis of heart trouble. In most of these people a careful study made it evident that there was at least an unhygienic condition of the heart muscle. This was in several instances relieved when the general metabolism of the person was looked after. So, the first function of the clinic seemed to be to afford relief of cardiac pain or of such symptoms as bad breathing or dropsy obviously due to the heart. The second useful function of the clinic, as shown more particularly in the case of the younger sufferers, was the appraisal of the heart condition in such a manner as to establish a fairly safe criterion to determine the amount of immediate and future activity that could safely be enjoyed by the patients.

Human Readjustment or Coordination of Structure and Function in the Organism as a Whole.—Dr. J. MADISON TAYLOR of Philadelphia read this paper. (See page 441.)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held January 13, 1921.

DR. MINER C. HILL IN THE CHAIR.

THE program of the evening was arranged in conjunction with the Babies' Welfare Federation for the New York Nutrition Council.

Care of Preschool Age Children at the Association for Improving the Condition of the Poor Community House.—Mr. JOHN C. GEBHART read this paper, in which he stated that the Association for Improving the Condition of the Poor for the past three years has been concentrating its efforts on three lines of work which they had found were necessary if child welfare work was to grow and develop. These were: (1) Prenatal care for the expectant mother (2) examination and supervision of preschool children, and (3) supervision of the mothers in the home. To ascertain conditions among preschool children a survey was begun in a colored district and then in an Italian district. The district selected was that bounded by Houston and Canal streets and Broadway, with a population of 32,335, of which 92 per cent. were Italians. In this locality there were about 1,400 persons to the block, exclusive of those who were there merely for business. Aliens they were and aliens they remained. Of the men, 75 per cent. were unnaturalized, and of the women 65 per cent. were illiterate. From April, 1919, to October, 1920, Dr. Schroeder examined 2,186 children in this district, 894 of whom were of preschool age. They had been particularly fortunate in being able to present so many children from the same neighborhood, the same racial stock, and often a number in the same family. The attempt was made to make a list of defects that should conform to other examinations of similar groups, but it was found that hardly any two investigators agreed as to what defects should be considered. They finally made a list of the main subdivisions of defects, omitting the insignificant ones. The statistical results were tabulated and showed in a general way that the greatest number of defects were those of the nose and throat; defects in nutrition ranked second; teeth third; orthopedic defects fourth; defects of the glands fifth; and defects of the abdomen sixth. In the group of preschool children 2,231 defects were discovered, or an average of 2½ defects per child; in the group of children from six to twelve years of age the average number of defects also numbered 2½ per child, while in the group from twelve to sixteen years of age the average was 1.8 defects per child. The whole number of defects meant little unless one knew their significance. Defects of the head were much higher in the first group than in the other groups, but these defects were mostly due to rickets and disappeared as the child grew older. There was little difference in the percentage of eye defects in the different groups. Thirty-four per cent. of the entire series had nose or throat defects. Operation for the removal of hypertrophied tonsils was advised less often in the preschool group than in the other groups. Of the preschool children 28 per cent. had defective teeth, while 96 per cent. of the children of school age had defective teeth. Defects of the lungs did not bulk large in this series; when such defects were found the children were referred to the tuberculosis clinics. Cardiac defects differed from some others in that the number of children showing such defect increased as the age of the children advanced. In the first group 4 per cent. had cardiac defects, while in the second and third groups 6 per cent. had such defects. This was a high percentage, as the number of cardiac defects in similar groups was usually about 2 per cent. Among the preschool children 55 per cent. of the cardiac defects were functional. The percentage of undernourished children was about the same for the first two groups. The dental work, and eye, ear, nose, and throat work was cared for by the schools in the usual way. Little could be done for orthopedic defects except to take such children to an orthopedic dispensary. Of the preschool children 24.6 had orthopedic defects. Most orthopedic defects were found to be due to rickets and plans were being made to prevent this kind of defect. Cardiac defects were cared for in the cardiac class at Bellevue. The public health work carried out as one of the activities of the Mulberry Community House had met with a ready response on the part of the people. The question of dealing with undernutrition in the preschool child had been a difficult one. It had been found that a weekly weighing in the presence of the mother was a very effective lesson in driving home the importance of fresh air, proper food, and rest. They were using a portable scales that the visiting nurse could easily carry with her. This statistical study was merely a byproduct of the work; the main object was to carry public health education to these people and to teach the need for supervision of the child of preschool age.

The Preschool Child.—Dr. MARK S. REUBEN read this paper, in which he asserted that the problem of the preschool child deserved more attention than it received at present. Children under five years of age constituted nearly 12 per cent. of the population; in this 12 per cent. of the population occurred 21 per cent. of all deaths in this country. In the registration area of the United States (1918) out of a total of 1,471,367 deaths, 306,143 were children under five years of age. The younger the preschool child the less apt it was to survive the fifth year. In children under five years but over one year of age the most important causes of death were the infectious diseases, respiratory diseases, intestinal disturbances, accidents and injuries, tuberculosis, diseases of the nervous system and of the circulatory system. The predisposing causes of mortality and morbidity at this age were the same as those encountered in the study of infant mortality. They were poverty, ignorance, and neglect. The importance of adequate family income, of domestic economy, and of hygienic surroundings and sanitary homes could not be overemphasized. Education like charity should begin at home. Hereditary diseases should be treated in parents before children were born. There was a higher mortality among illegitimate children. Where the proper indications were present the physician should advise women how to prevent conception. This did not mean that the advice should be given by women of deficient mentality and of doubtful sincerity. The problem which the child under two years presented was somewhat different from that of the preschool child; whereas with the former we were more concerned with reducing the death rate, in the latter our main efforts should be directed to prevent disease. The relation of the preschool age problem to that of the school age was the same as that of prenatal work to the reduction of mortality from congenital causes; to reduce mortality and morbidity of school children we must not neglect those of preschool age. It was most important that minor diseases should receive attention at this age. A summary of the methods which Dr. Reuben suggested for the reduction of mortality and morbidity at this age was as follows: (1) Complete registration of births; accurate statistics as to number and distribution of children. (2) Complete physical and mental examination of all children of preschool age. (3) Constant observation, periodic examination, supervision of diet and home conditions, and correction of all defects. Special health centers and schools. (4) Reliable standards as to height and weight of children of this age must be established. (5) Health education is the fundamental need of the day. Education is the panacea for ignorance. Academic colleges should provide information on health matters to their pupils; school teachers should receive similar instruction. Women should be especially trained for public health work. There should be a differentiation of public health nurses. The nurse should treat the sick; the public health worker should teach how to prevent the development of disease and how to maintain health. All school children should receive elementary instruction in diet and hygiene, and the formation of good health habits be stimulated. All medical students should receive adequate instruction in diet, hygiene, and public health work. (6) Permanent institutional care should be discouraged; all day nurseries and babies boarded out should be under strict medical supervision. (7) Playgrounds and play-centers should be established (7,000

children die every year from accidents and injuries). (8) Adequate wages, sanitary housing, and economical use of incomes are essential requirements. (9) The importance of attending to minor ailments must be emphasized. (10) To reduce morbidity and mortality from infectious diseases precautions must be taken against the spread of these diseases. The younger the child the worse the prognosis and more likely it is to have complications. Our precautions against pertussis are inadequate. The importance of vaccinating against diphtheria (with toxin-antitoxin) those who are not immune as shown by the Schick test and against smallpox should be emphasized. (11) To avoid respiratory diseases, boarding must be avoided; sanitary homes are essential. Rickets, infectious diseases, and adenoids predispose to respiratory disease. Direct contact with those infected must be avoided. Therefore, proper feeding, proper hygienic surroundings, and proper clothing are essential; we must remove adenoids, and avoid all contact with patients who are suffering from any infection. (12) Digestive disturbances are often the result of improper feeding during the first two years of life. Breast feeding should always be encouraged. A quart of milk every day for every child should be insisted upon as the basis of a rational diet. (13) The child of tuberculous parents should be removed from the focus of infection (preventoria). The luetic parent should be treated before the mother conceives, during pregnancy, and, in fact, after the birth of the child. (4) Cardiac diseases can be reduced by greater attention to the infectious diseases and avoidance and removal of all focal infections in tonsils, teeth, and sinuses. (15) The great majority of cases of malnutrition is due to adequate causes such as physical defects, improper food, habits, and overfatigue; and only in a minor degree is it due to poverty, inheritance, and other obscure causes. (16) Proper diet and dental hygiene are the answer to dental caries. The wholesale removal of teeth in children for inadequate causes should be discouraged; filling, when possible, should be preferred to removal. (17) Diseased tonsils and adenoids should be removed. (18) The deformed (physically and mentally) and the delinquent child should receive special care.

Standard and Method of Health Work Among Children of Preschool Age.—Dr. ROBERT D. CURTIS read this paper in which he stated that the need for continued supervision of children beyond the age of infancy had been convincingly presented and he felt that there was no question on this point. The important thing was to devise a workable scheme of putting it into effect. There was no source to which one could go for information as how to establish such work. Small beginnings had been made, it was true, but many links were as yet imperfect. The period of childhood following weaning was a very dangerous one, for at this time one had not only the problems of feeding but new problems having to do with environment came in. As soon as the child began to get about and to derive its food from various sources it was exposed to infection in many ways and was influenced by many conditions in its environment. Anything that affected the family for good or evil had a corresponding effect upon the child. A realization of the need for child welfare work had brought many agencies into the field. The danger of overlapping work by these various organizations had been greatly lessened by the Confidential Exchange, which aimed to correlate different child welfare activities. It seemed too much to expect the domestic mother to realize the need for continued supervision of the child after it had passed beyond the period of infancy. Mothers, as a rule, never felt competent to rely upon their own judgment where an infant was concerned, but when it came to the older child she seemed not to question her ability to assume the responsibility, and seldom asked advice except for some very obvious defect. If conferences for preschool children were to be well attended means must be devised to get the parents to bring the children. Under an ideal system all the children in a preschool conference would come as graduates of the infant welfare station. The infant welfare conference offered the greatest opportunity for educating the mothers. All charitable and social agencies should join hands to educate the parents to the need of supervision for older children. Dr. Curtis said he felt that medical men and social workers would see the need of supervision for the preschool age, but he felt they would not make an appeal to most mothers if they confined themselves purely to dealing with defects such as tonsils and adenoids, and the repair of dental defects, but he thought that if they added vaccination, postural work, and dental hygiene these would make an appeal. Faulty posture was seldom given the attention it deserved and postural work might be considered as preventive medicine. With the establishment of dental hygiene and postural instruction the parents would be given something they would appreciate. After mothers were convinced that this work was desirable it still remained to convince the children as well. If the conference was not made attractive to the child he would not care to come and the mother would yield to his inclination to stay away. In order to make an appeal to the child a story-teller and books were provided and perhaps a sand box. It was necessary to have a separate room for the examinations. It was a rather strange thing that mothers did not object to having the defects of their babies pointed out before others, but disliked to have their older children exposed to view unless they were unusually well formed. The success of these conferences depended almost entirely upon the personality of the physician and other workers. A pleasant relation must be maintained with both children and mothers. For the physician accustomed to think in terms of dieteties, anatomy, and medicine and at the same time to keep himself on the child's mental level was a rather difficult task to perform. By keeping on the child's mental level he did not mean having recourse to buffoonery, but maintaining a sympathetic and approachable attitude. The physical examination was relatively more important than other features. The well child should be examined once in three months; those below normal as often as was necessary. In Boston college students taking household economics and those taking kindergarten courses volunteered as assistants, the latter acting as story-tellers. A doctor, an able nurse, and a dietetician formed an essential part of the staff. After infancy the work of supervising children increased in amount at a surprising rate. Neither a nurse nor a dietetician was exactly fitted to do the work; they should have to find a plan to secure persons who had a broader training than either a dietetician or a nurse. The usual defects found in children of school age were also found in those of preschool age. Tuberculosis at this age, however, was very rare. For those cases that were tuberculous, a tuberculosis expert should be available. The treatment of conditions of the nasopharynx was one of the most important parts of this work. There had been a good deal of criticism on the ground that tonsillectomies were performed. He was sure the number of harmless tonsils removed far exceeded the number of diseased ones left in place. Deformities of bones, spine, and joints in the majority of cases were the results of rickets and malnutrition. These defects did not exist in children who had been under supervision from infancy. Dental caries was by far the most frequent defect in children of all ages. The supervision of children of preschool age would insure proper care of the first teeth and would preserve them in good condition until the second permanent teeth came in. Malnutrition was an expression of disease that disappeared when the conditions producing it were corrected. The preschool care of children should provide for the care of those with tuberculosis, for attention to the ears, nose, and throat; it should provide for orthopedic, dental, and nutritional work. Even with the care of all these departments a child might remain subnormal, and in such children a complete change of environment was important. Every plan of supervision should provide opportunities for education in mental hygiene by directing play, teaching discipline, and preparing the child for beginning work later on. Most communities had arrangements for the care of infectious diseases. Measles, scarlet fever, and diphtheria were cared for in hospitals. Whooping cough, which caused more deaths than any one of the other diseases, was not cared for in hospitals, was spread by child carriers, and was allowed to go untreated. If the reports regarding the value of pertussis vaccine continued to be confirmed, it should be

made available in clinics. The maximum number of children that could be properly supervised by one worker was 175, and she would have 35 new children each year, while 35 would graduate from her care. He would give to each worker a group of children of fairly equal age distribution as the procedure to be followed with older groups of children was different from the established procedure for infants, since, in addition to problems of hygiene, those of environment and gaining the cooperation of the mother and child entered in.

Dr. CHARLES HENDEE SMITH said the papers of the evening had brought out a tremendous number of things in regard to the care and observation of children of preschool age. One might talk indefinitely on any one of them. One thing that had impressed him most of all was the necessity of continuous observation of children from infancy up. This meant that the cases must be classified or grouped first. It had been proven time and again that results obtained in any group were directly in proportion to the effort expanded. This had been shown in malnutrition, cardiac, and feeding classes and was equally true for the preschool children. This fact was so obvious that it needed no reiteration, but the question before them was the way in which to attack it. It meant a tremendous number of preschool clinics. It was not a problem similar to that of malnutrition or cardiac disease in which only a certain percentage of children were involved, but all children from two to six years of age must be observed. This meant, first, that the hospitals and dispensaries must separate preschool children from older children and the child must be automatically graduated from the infant group to the preschool group. If a child did not return for observation he must be followed up, not only by the doctor, but a follow-up of the family must be carried out as far as possible within the limitations of their staffs by social agencies. Such a plan had been in operation at Bellevue for two or three years. At this age the cases of intercurrent illness (cold or sore throat, etc.) occurred so often that the mother came for treatment of each child several times a year without much follow-up work. Vaccination, Dr. Smith said, was a part of medical responsibility and if properly assumed it helped to rivet the affection of the family on the hospital or clinic. It was interesting to see a meeting of this kind and size talking about common diet habits and hygiene, and to realize the large number of people trying to advance the new methods of teaching mothers these matters. A few years ago these would scarcely have been considered medical subjects. It was encouraging to see the change of heart that had come over us in the last ten years.

Dr. HILL said that in the Bowling Green Neighborhood Association the mothers were at first unwilling to bring their children to the health center for examination when they were apparently well. They were anxious, however, to have their children vaccinated and by holding out vaccination as an inducement they were able to draw a large number of children to the health center, where a physical examination was obtained before the child was vaccinated.

Mr. GEORGE R. BEDINGER of the New York Chapter of the American Red Cross said he had been in the field such a short time that he could add but little to the discussion. In the work they had begun they were appealing very strongly for the preschool child, and he hoped that as time passed and their work developed it could be extended into this field. At the present time the Red Cross stations were situated near public schools, settlement houses, or neighborhood centers, and in connection with them there were dental and nutritional clinics, and the needs of the younger children were recognized. From the infant welfare clinic at Greenwich House a child could be passed on to the supervision of their nutritional clinic and dental hygiene clinic and there could be referred to a pediatrician. The problem of the preschool child had been recognized for a number of years and a great deal of praise should be given to the hospitals, the A. I. C. P. Community House, the Bowling Green Association, and others who really had done something in this field.

Dr. HENRY DWIGHT CHAPIN stated that he happened to be a member of the Governor's Reconstruction Commission and chairman of the Health Section and had taken a great deal of interest in trying to find out the mortality and morbidity in different parts of the State, particularly in regard to the child. He had found that the preschool child was the neglected child. He had sent out a questionnaire and the replies showed that in 29 communities with 48 infant welfare stations and 7 prenatal clinics there were only 5 clinics for preschool children. In 34 municipalities there were 6 preschool clinics. In New York City there were 83 welfare stations that did little for the preschool child. There were 116 child welfare stations at 67 points in the up-State area. These might do something for the preschool child. Dr. Chapin said he could not altogether agree with Dr. Smith about going back and beginning from the public schools. He thought we should work forward from the infant welfare stations. This work could be extended. It was already organized and in the field. They had places and the work could be extended to include the preschool age. This seemed a comparatively easy way to enlarge the work of the infant welfare stations already in existence and doing such good work. Dr. Chapin stated that he had recommended to the Governor that health centers be established, since in the up-State sections attention to disease was very often inadequate. If we had health centers it would solve many problems, but particularly the problem of the preschool child.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF MARYLAND.

December 14-17, 1920.

ANATOMY.

1. Describe the fibula—articulations—muscular attachments.
2. What muscles or tendons cross the knee joint? Which of them are extensors.
3. Origin and distribution of ophthalmic nerve.
4. Name all structures severed by cross section at middle of arm.
5. Name structures passing through two of these three foramina: (*a*) Foramen magnum, (*b*) Sphenoidal foramen, (*c*) Optic foramen.
6. Minute anatomy of kidney.
7. Attachments, action, and nerve supply of following muscles: Triceps extensor cubiti, gluteus maximus, serratus magnus, scalenus anticus.
8. Where would you locate lesion in case of pure motor aphasia?
9. What variety of epithelium covers the mucous membrane of the mouth? Of the nose?
10. Name openings into pharynx.

PHYSIOLOGY.

1. Describe the physiology of respiration.
2. Give a general classification of foods and state the functions of each class.
3. Name in order the different divisions of the gastrointestinal tract and state the functions of each.
4. Urine. Reaction, specific gravity, average amount voided in 24 hours, amount of urea in 24 hours. What condition will alter the specific gravity?
5. Describe a method of producing artificial respiration. How long should it be continued?
6. Give the functions of the spinal cord.
7. Blood. Specific gravity, reaction, chief constituents, cause of color, ratio to body weight.
8. What changes take place in the heart at birth? What would be the result if these changes did not take place?
9. Where is bile formed? How does it get into the intestinal canal? What are its functions?
10. Define briefly the tissue and mechanisms of digestion and absorption.

ANSWERS.

ANATOMY.

1. The *Fibula* is a long, slender bone, situated in the leg, to the outer side of the tibia. It consists of a

shaft and two extremities. The upper extremity is called the head, and it articulates with the external tuberosity of the tibia; on the head is the styloid process, to which the tendon of the biceps is attached. The lower part of the fibula forms the external malleolus, the inner surface of which articulates with the astragalus, and the posterior part of which is grooved for the tendons of the peronei muscles. The shaft has three surfaces and three borders; to the external surface are attached two peronei muscles; to the internal surface is attached the interosseous membrane. The fibula *articulates* with two bones, the tibia and the astragalus. *Nine muscles are attached* to the fibula: The biceps, to the styloid process; the extensor longus digitorum, extensor proprius pollicis, and peroneus tertius, to the internal surface; the soleus, tibialis posticus, and flexor longus pollicis, to the posterior surface; and the peroneus longus and brevis, to the external surface.

2. *Muscles and tendons which cross the knee joint*.—Vastus externus, vastus internus, crureus, rectus femoris, popliteus, sartorius, gracilis, biceps, semimembranosus, semitendinosus, popliteus. Of these, the first four named are extensors.

3. *The ophthalmic nerve* is the first branch of the fifth cranial nerve; it supplies sensation to the conjunctiva and skin of the upper eyelid, cornea, skin of forehead and nose, lacrymal glands, and mucous membrane of the nose.

4. *In cross section at the middle of the arm*, the following structures are severed: *Skin; fascia; muscles*, biceps, brachialis anticus, coraco-brachialis triceps; *arteries*, brachial, superior profunda, inferior profunda; *nerves*, median, ulnar, musculo-spiral, internal cutaneous, musculocutaneous; *bone*, the humerus.

5. *Structures passing through the foramen magnum*.—Medulla oblongata and membranes, vertebral arteries, spinal accessory nerves, anterior and posterior spinal arteries, and alar ligaments.

Structures passing through sphenoidal foramen.—Branches of lacrymal and middle meningeal arteries; ophthalmic vein; third, fourth, first division of fifth, and sixth cranial nerves; filaments of sympathetic nerve.

Structures passing through optic foramen.—Ophthalmic artery and optic nerve.

6. *Minute anatomy of kidney*.—"The kidney is a compound, tubular gland composed of microscopic tubules whose function it is to secrete from the blood those waste products which collectively constitute the urine. If the apex of each pyramid be examined with a lens, it will present a number of small orifices, which are the beginning of the uriniferous tubules. From this point the tubules pass outward in a straight but somewhat divergent manner toward the cortex, giving off at acute angles a number of branches. From the apex to the base of the pyramids they are known as the tubules of Bellini. In the cortical portion of the kidney each tubule becomes enlarged and twisted, and after pursuing an extremely convoluted course, turns backward into the medullary portion for some distance, forming the descending limb of Henle's loop; it then turns upon itself, forming the ascending limb of the loop, re-enters the cortex, again expands, and finally terminates in a spheric enlargement known as *Müller's* or *Bowman's capsule*. Within this cansule is contained a small tuft of blood vessels, constituting the *glomerulus*, or *Malpighian corpuscle*. Each tubule consists of a basement membrane lined by epithelium cells throughout its entire extent. The tubule and its contained epithelium vary in shape and size in different parts of its course. The termination of the convoluted tube consists of a little sac or capsule, which is ovoid in shape and measures about 1/200 of an inch. This capsule is lined by a layer of flattened epithelial cells, which is also reflected over the surface of the glomerulus. During the periods of secretory activity the blood vessels of the glomerulus become filled with blood, so that the cavity of the sac is almost obliterated; after secretory activity the blood vessels contract and the sac-cavity becomes enlarged. In that portion of the tubule lying between the cansule and Henle's loop the epithelial cells are cuboid in shape; in Henle's loop they are flattened, while in the remainder of the tubule they are cuboid and columnar." (Brubaker's *Physiology*.)

7. TRICEPS EXTENSOR CUBITI. *Origin*, immediately below glenoid cavity of scapula, posterior surface of shaft of humerus between insertion of teres minor and upper part of musculospiral groove, external border of humerus and external muscular septum, posterior surface of shaft of humerus below the musculospiral groove, and internal border of humerus. *Insertion*, olecranon process of ulna and deep fascia of forearm. *Action*, extensor of forearm and elbow joint. *Nerve supply*, the musculospiral.

GLUTEUS MAXIMUS. *Origin*, from dorsum of ilium, behind the superior curved line, from sacrum and coccyx and from great sacrosciatic ligament. *Insertion*. Fascia lata on outer side of thigh and into a line running from the great trochanter of femur to the linea aspera. *Action*. Extension, abduction, and external rotation of hip joint. *Nerve supply*. Inferior gluteal branch of small sciatic nerve.

SERRATUS MAGNUS. *Origin*, outer surface and upper border of upper eight ribs and from aponeurosis of the corresponding intercostal muscles. *Insertion*, the ventral aspect of the vertebral border of the scapula. *Action*, it carries the scapula forward and raises its vertebral border; it is concerned in the act of pushing; it raises the acromion process and assists in raising the arm. *Nerve supply*, posterior thoracic.

SCALENUS ANTICUS. *Origin*. From tubercle of first rib. *Insertion*. Into anterior tubercles and transverse processes of third to sixth cervical vertebræ. *Action*. To flex head and bend the head to the same side; also to aid in inspiration. *Nerve supply*. Supraclavicular branch of brachial plexus.

8. *In case of pure motor aphasia*, the lesion is in the posterior part of the third frontal convolution of the brain (Broca's convolution), just in front of the center of the muscles governing speech; the lesion is on the left side in right-handed persons.

9. The *mucous membrane of the mouth* is covered by stratified squamous epithelium.

The *mucous membrane of the nose* is covered by columnar epithelium; this is ciliated in the respiratory portion, and non-ciliated in the rest.

10. *Openings into the pharynx* are seven in number: two Eustachian tubes, two posterior nares, mouth, esophagus, and larynx.

PHYSIOLOGY.

1. *Respiration* means the taking in of oxygen and the elimination of carbon dioxide. The respiratory act consists of inpiration and expiration. The origin of the impulses is at the respiratory center in the medulla. The phrenics and intercostals are the chief nerves conveying the impulses; and they are distributed to the diaphragm and intercostal muscles, respectively. External respiration is the interchange that takes place between the blood and the gases in the lungs; internal respiration is the interchange that takes place between the blood and the tissues of the body. Respiration causes changes in the air as follows:

	EXPIRED AIR	INSPIRED AIR
Oxygen	16.6 per cent.	21 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon Dioxide..	4.4 per cent.	0.04 per cent.
Other gases	Often present.	Rare.
Watery vapor ...	Saturated.	Variable.
Temperature	That of the body.	Variable.
Volume	Diminished.	Varies.
Bacteria	None.	Always present.
Dust	None.	Always present.

Chemical changes in the blood in respiration. Venous blood is brought to the lungs for aeration (external respiration); after aeration it is carried to the tissues, where internal respiration occurs.

External respiration. Between the air in the alveoli of the lungs and the blood there exists the endothelium of the capillaries and the epithelium of the walls of the acini. Through these two layers the interchanges between the air and the blood must take place. Inspired air contains 21 per cent. of oxygen; expired air contains 16 per cent. of oxygen; therefore 5 per cent. of oxygen is absorbed. The oxygen tension in venous blood as it reaches the lung is low, and so by diffusion of gases oxygen passes from the air in the alveoli to the blood until an equilibrium of tension is reached.

But it is found that the oxygen tension of arterial blood is above that of air, and this extra amount of oxygen is taken into the blood by the selective power of the epithelium lining the acini of the lungs. The oxygen is then combined loosely with the hemoglobin of the blood, forming oxyhemoglobin. The oxygen is combined with the hematin part of the hemoglobin, and the amount absorbed depends on the amount of iron in the hematin (usually about 0.4 per cent.). The oxyhemoglobin is carried by the blood to the tissues. The amount of carbon dioxide in inspired air is 0.04 per cent.; in expired air it is 4.4 per cent.; so that, roughly, about 4 per cent. of carbon dioxide is expired. The carbon dioxide tension in venous blood is high; in alveolar air it is low; and so by diffusion carbon dioxide leaves the blood and passes into the alveolar air until equilibrium is reached and the carbon dioxide is prevented from returning into arterial blood again by the selective action (or biotic activity) of the epithelium lining the acini. The nitrogen of the air is only a diluent, and does not enter into any chemical action. One hundred volumes of blood yield about sixty volumes of gas:

	VOLS. OF OXYGEN	VOLS. OF CARBON DIOXIDE
100 Vols. of arterial blood	20	40
100 Vols. of venous blood	12	48

Internal respiration. Arterial blood leaves the lungs and is carried to the tissues, where the oxygen from the oxyhemoglobin is absorbed by the molecules of proteins, fats and carbohydrates in the tissues; oxidation does not occur immediately, but eventually it does. Some of the oxygen is used to form water, which passes into the blood and is excreted by the kidneys, skin and lungs; but most of the oxygen goes to form carbon dioxide, and this passes back into the venous capillaries. This oxidation is aided by tissue enzymes called oxidases. The carbon dioxide returns to the lungs by the venous blood, in various ways: absorbed to the protein molecules, as Na_2CO_3 and $NaHCO_3$ and a small amount is free in the blood.

2. *Classification of foods:*

I. Inorganic. { Water. / Salts.

II. Organic. { Non-nitrogenous. { Carbohydrates. / Fats. / Nitrogenous—Proteids.

Functions of water.—It enters into the composition of all the tissues of the body, and helps to maintain their consistency, elasticity and pliability; it distributes heat and regulates the body temperature; it moistens surfaces and prevents friction; it maintains the fluidity of the body fluids and enables them to perform their functions.

Function of salts.—They aid in tissue formation, regulate energy and nutrition, regulate the specific gravity and chemical reaction of the blood and other fluids of the body, control the rate of absorption, and they take part in various chemical reactions in the body (such as the formation of hydrochloric acid in the stomach, from sodium chloride).

Function of carbohydrates.—They supply heat and energy, save tissue waste, and spare the proteids.

Function of fats.—They supply energy and heat, nourish the nervous tissues, serve as a covering and protection in the body.

Function of proteids.—Formation and repair of tissues and fluids of the body. Regulation of the absorption and utilization of oxygen. May also form fat and carbohydrate, and yield energy sometimes.

3. *The divisions of the alimentary tract* are: Mouth (with tongue, teeth, and salivary glands), pharynx, esophagus, stomach, small intestine (duodenum jejunum, ileum) large intestine (cecum, ascending colon, transverse colon, descending colon, sigmoid flexure, and rectum), with liver and pancreas.

In the *mouth*, the food is masticated and mixed with saliva; salty substances and sugar may be dissolved, boiled starches are converted into maltose by the action of the ptyalin. In the *stomach* the food is mixed with gastric juice, more thoroughly triturated, moved around the stomach, and finally expelled into the duodenum. In the stomach the proteins are split up into proteoses and peptones by the pepsin of the gastric juice, and certain bacteria are killed by the hydrochloric acid; starches are not affected; fats are split up by a gastric lipase.

In the *small intestine*, digestion is continued, the proteins being further digested (by the trypsin of the pancreatic juice) into polypeptides and amino-acids; the fats are split up into fatty acids and glycerin; the starches are converted into maltose; and absorption takes place. In the *large intestine*, water is further absorbed, bacterial changes occur, and the residue is prepared for expulsion.

The *functions of the liver* are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

The *functions of the pancreas* are: (*a*) The secretion of the pancreatic juice, which (1) changes proteids into proteoses and peptones, and afterward decomposes them into polypeptides and amino-acids; (2) converts starch into maltose; (3) emulsifies and saponifies fats, and (4) causes milk to curdle. (*b*) The manufacture of an internal secretion.

4. URINE. *Reaction,* acid. *Specific gravity,* about 1,015 to 1,025. *Average amount voided in 24 hours,* about 45 to 50 ounces. *Amount of urea excreted in 24 hours,* about 500 grains. *The specific gravity may be increased,* in: Fevers, parenchymatous nephritis, diabetes mellitus; *it is low* in: diabetes insipidus, chronic interstitial nephritis, functional nervous disorders. Naturally the specific gravity varies with the quantity of urine voided.

5. *Schafer's method of artificial respiration.*—"The subject is laid on the ground in the prone position, with a thick folded garment under his chest. The operator kneels by his side or athwart him facing his head, and places his hands on each side over the lower ribs. He slowly throws the weight of his body forward, and thus presses upon the thorax of the subject, and forces air out of the lungs; he then gradually relaxes the pressure by bringing his body up again, but without removing his hands. This is repeated regularly at the rate of twelve to fifteen times a minute until normal respiration begins, or until all hope of restoration is given up." (Halliburton's *Physiology.*)

6. The *functions of the spinal cord* are: (1) The conduction of nerve impulses; (2) reflex action; (3) coordination; it also contains special centers which preside over definite functions.

In the spinal cord: (*a*) The white substance simply conducts nerve impulses; (*b*) the gray substance contains groups of cells which act as centers for and distributors of nerve impulses, and are also concerned in reflexes; (*c*) the anterior cornua have a motor and trophic function; (*d*) the posterior cornua are sensory.

The *special centers in the spinal cord* are: (1) Cilio spinal center and centers, (2) for sphincter of bladder, (3) for sphincter of rectum, (4) for erection, (5) for contraction of uterus, (6) for maintaining tonus of muscles.

7. BLOOD. *Specific gravity,* about 1,055 to 1,062. *Reaction,* alkaline. *Chief constituents* are plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteins, fat, and inorganic salts). The *white corpuscles* consist of water and solids (protein, leuconuclein, lecithin, histon, etc.). *Cause of color,* the presence of hemoglobin and its derivatives. *Ratio to body weight,* about one-twentieth of the weight of the body.

8. *The changes that take place in the heart at birth* are: (1) The Eustachian valve atrophies; and (2) the foramen ovale closes. If these changes do not take place, the blood does not become sufficiently oxidized, and the infant suffers from cyanosis. If the ductus arteriosus also fails to close, the infant dies.

9. *Bile* is formed in the liver cells. From the liver, the bile is conveyed to the gall-bladder, and then by way of the cystic duct and common bile duct to the duodenum. *Function of bile* is: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the

intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

10. DIGESTION. (1) *In the mouth* the food is crushed, mixed with saliva, and reduced to a pulp; a certain amount of starch is converted into maltose and rendered slightly alkaline. Fats and proteids are unaltered. (2) *In the stomach*, the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved, and fats are set free. Proteids are dissolved and proteoses and peptones formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine. (3) In the *small intestine* the chyme is mixed with the bile and the pancreatic juice; the reactions become alkaline. Proteids are split up into proteoses and peptones, and these are further split into polypeptides and amino-acids; starches are converted into maltose; fats are emulsified and saponified; and the products of digestion are now ready for absorption.

The process of digestion is carried on mainly by various enzymes:

DIGESTIVE SECRETION.	ENZYMES.	ACTION.
Saliva	Pytalin.	Changes starch into dextrin and sugar.
Gastric juice...	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic juice.	Trypsin.	Changes proteids into proteoses and peptones, and afterward decomposes them into polypeptides and amino-acids; in an alkaline medium.
	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.

Absorption is the process by which the products of digestion are taken up into the general circulation. It occurs with greatest activity in the villi of the small intestine.

The products of digestion find their way into the blood by two routes: (1) By the blood vessels of the gastrointestinal tract, which unite to form the portal vein; and (2) by the lymph vessels of the small intestine, which converge to empty into the thoracic duct. The water, inorganic salts, proteids and sugar go by way of the portal vein to the ascending vena cava; and the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular veins.

The process by which absorption is accomplished is partly physical (osmosis and filtration), and is also due in part to selective action. To be absorbed by the blood vessels or lacteals the substances must be in a fluid state, and the more dilute the solution the more rapid the absorption. The absorbed matter must be rapidly removed and fresh blood supplied to the capillaries.

(To be continued.)

Placental Transmission of Epidemic Encephalitis.—Mercier and two others report a case of myoclonic encephalitis in a gravida near term; although the child exhibited the picture of myoclonic encephalitis it nevertheless survived. The disease of the mother did not in the least hasten labor which was clearly full term.—*Gazette des Hôpitaux.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SOCIAL ASPECTS OF THE TREATMENT OF THE INSANE. By JACOB A. GOLDBERG, M.D. 247 pages. Published by Longmans, Green & Co., New York.

TWENTIETH ANNUAL REPORT MORTALITY STATISTICS 1919. 616 pages. Published at the Government Printing Office, Washington.

DIABETES MELLITUS. By H. O. MOSENTHAL. 29 page book and set of pads in case. Price, $6.50. Published by Paul B. Hoeber, New York City.

GENERAL PATHOLOGY. By HORST OERTEL. 357 pages. Price, $5. Published by Paul B. Hoeber, New York City.

THE ASSESSMENT OF PHYSICAL FITNESS. By GEORGES DREYER and G. F. HANSON 127 pages. Price, $3.50. Published by Paul B. Hoeber, New York City.

ANXIETY HYSTERIA. By C. H. L. RIXON and D. MATTHEW. 124 pages, with frontispiece. Price, $1.50. Published by Paul B. Hoeber, New York City.

DIE LUNGENTUBERKULOSE IM RÖNTGENBILDE. By Dr. MAX COHN. 48 pages, with 10 illustrations and 3 plates. Published by Johann A. Barth, Leipzig.

ASILO COLONIA DE MAGDALENA (Memoria correspondiente al ano de 1920). 114 pages, with tables. Published by the Sociedad de Beneficencia Publica de Lima.

OPERATIVE SURGERY. By Dr. J. SHELTON HORSLEY. 721 pages, with 613 illustrations. Price, $10. Published by C. V. Mosby Company, St. Louis.

MEDICAL EDUCATION IN EARLY NEW YORK. By Dr. SAMUEL BARD. 28 pages, with frontispiece. Published by Columbia Univ. Press, New York.

THE CLINICAL EXAMINATION OF DISEASES OF THE LUNGS. By E. M. BROCKBANK and ALBERT RAMSBOTTOM. 88 pages, with illustrations. Price, $1.50. Published by Paul B. Hoeber, New York City.

THE MANAGEMENT OF MEN. By EDWARD L. MUNSON. 801 pages, with illustrations. Published by Henry Holt & Company, New York City.

CHIRURGISCHE OPERATIONSLEHRE. By Prof. Dr. FRIEDRICH PELS LEUSDEN. 800 pages, with 778 illustrations. Price, 200 marks. Published by Urban & Schwarzenberg, Berlin.

MANUAL OF MIDWIFERY. By Drs. JELLETT and MADILL. 1199 pages with 20 plates and 570 illustrations. Price $10. Published by William Wood & Company, New York.

THE UNCONSCIOUS. By Dr. MORTON PRINCE. 654 pages. Price $3. Published by the MacMillan Company, New York.

THE OXFORD MEDICINE. Edited by HENRY A. CHRISTIAN, M.D., and Sir JAMES MACKENZIE, M.D. Volume IV. 938 pages. Illustrated. Published by the Oxford University Press, American Branch, New York.

MENTAL HOSPITAL MANUAL. By JOHN MACARTHUR. 215 pages. Published by the Oxford University Press, American Branch, New York.

THE SURGICAL CLINICS OF NORTH AMERICA. June, 1921. Vol. 1; No. 3. Published by W. B. Saunders Company, Philadelphia.

THE MEDICAL CLINICS OF NORTH AMERICA. May, 1921. Index number. Published by W. B. Saunders Company, Philadelphia.

PATHOLOGIE UND THERAPIE DES HÄMOLYTISCHEN IKTERUS. By Prof. Dr. M. MOSSE. 50 pages. Published by Carl Marhold.

REPORT OF THE HEALTH DEPARTMENT OF THE PANAMA CANAL FOR THE CALENDAR YEAR 1920. By Col. H. C. FISHER. Published by the Panama Canal Press, Mount Hope, C. Z.

PROCEEDINGS OF THE ELEVENTH ANNUAL MEETING OF THE MEDICAL SECTION OF THE AMERICAN LIFE CONVENTION.

THIRTY-SIXTH ANNUAL REPORT MONTEFIORE HOSPITAL FOR CHRONIC DISEASES.

Miscellany.

NEW BOOKS AND OLD.

XIII. SOME BOOKS ABOUT PARACELSUS.

BY JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

It has always been a matter of surprise to me that no one has ever written a play using Paracelsus as the central figure. Whatever one's opinions are concerning him, there is no question that he is one of the outstanding figures of the beginning of the Renaissance. His teachings and his strenuous life had much to do with the breaking of the shackles of scholasticism, much more indeed than his contemporaries or his critics for a couple hundred years after his death were willing to admit. It is true that the brilliant Viennese playwright, Arthur Schnitzler, has written a little curtain raiser in one act which does not place Paracelsus in a very enviable light. There is also a dramatic dream play in five acts by Arthur Müller called "Paracelsus und der Träumer", which was published about 1912 in Vienna. Browning's poem is familiar at least by name to most of my readers but the story of the man has yet to be presented in play form. If Sacha Guitry could make a play with Pasteur as its central figure, I wonder what the result would be if a man like Sudermann or Wedekind should turn his attention to this brilliant erratic pioneer of medical and chemical thought?

The bibliography of Theophrastus Bombastus Von Hohenheim is considerable, most of it in German, but other writers of other nationalities have written his life and essays on his books and opinions. The chief students in German have been Friederich Mook, who wrote a critical study in 1876; Karl Aberle, who opened Paracelsus' grave and made a study of his skull and skeleton and of the various paintings and drawings that had been made of him during life; Karl Sudhoff, who published extensive studies both alone and in connection with Eduard Schubert and Franz Strunz. The writings of Paracelsus have been translated and edited by Arthur Edward Waite and published in two volumes in London in 1894, and it is to this monumental work that most students unfamiliar with the German language turn.

In addition to the other publications there is the life of Paracelsus and his teachings by Franz Hartmann, the second edition of which was published in 1896. This book which I can recommend as a soporific, for I have had it on my bedside table for a year and have not yet succeeded in finishing it, deals largely with the magical and mystical opinions of Paracelsus and to what Hartmann calls his spiritual truths. As Hartmann says in his preface:

> Paracelsus threw pearls before the swine, and was scoffed at by the ignorant, his reputation was torn by the dogs of envy and hate, and he was treacherously killed by his enemies. But although his physical body returned to the elements out of which it was formed, his genius still lives; and as the eyes of the world become better opened to an understanding of spiritual truths, he appears to illuminate the world of occult science, and to penetrate deep into the hearts of the coming generation, to warm the soil out of which the science of the coming century will grow.

A very readable though somewhat imaginative life was written by Anna M. Stoddart in 1911. This book contains a number of illustrations showing the various portraits that have come down to us. The first is the handsome portrait of the self-satisfied man at twenty-four which was painted by Scorel in 1517 and is now in the Louvre gallery, and the last is one after an engraving from a portrait made at Laibach or Vienna when he was forty-seven years old, showing the baldheaded, disappointed, sad student, marked by the trials through which he had been.

The most recent contribution is by John Maxson Stillman, Emeritus Professor of Chemistry, Stanford University. This, as the title page says, is about the personality and influence of Paracelsus as physician, chemist, and reformer. This little book gives a very delightful account, containing numerous quotations newly translated from the text as originally printed. Both Stoddart and Stillman recognize the great service that Paracelsus did for medical and chemical learning and so for humanity.

Paracelsus was born at Einsiedeln in Switzerland, December 17, 1493. In spite of the fact that he speaks frequently of his common origin he came of a good family, bearing a crest and his father was a physician before him. When the boy was about nine years old his father changed his residence to Villach in Carinthia. In this town there was a mining school founded by the Fuggers, of Augsburg, who were the Rockefellers and Carnegies of that day. It is highly probable that Paracelsus got his early training in this school and so had his attention turned to chemistry and metallurgy. At twenty-two he spent nearly a year in the mines and laboratories at Schwatz in the Tyrol. From this time until his death he was a great traveller, moving from place to place, almost always poor, but with his wonderful personality almost always successful in one way or another. His wanderings have been studied and more or less accurately outlined by R. J. Hartmann. After he left the mines he seems to have served as an army surgeon in Denmark and Sweden. He also travelled in England, France, and Belgium. It is not known whether he ever received a degree of Doctor of Medicine or not during his life.

His opponents said that he had not, but he disdainfully refused to make any comment. He was appointed City Physician at Basle, which position carried with it the duties of a Professor of Medicine. It is said that he owed this appointment to Johann Froben, the book publisher of Basle, who suffering from a painful illness sent for Paracelsus and on receiving speedy relief, the friends of Froben living with him prevailed on the city authorities to fill the position which was vacant at the time. Paracelsus had studied, travelled, and thought, and as he was a man of unusual self-assurance he entered into his new duties with a zeal which, while commendable, was far from politic.

It must be remembered, to understand Paracelsus or any of the other men of his period, that at the time he lived medical practice had fallen to a very low ebb owing to the fact that for a thousand

years or more there had been very little in the way of research and all that was done was to consult the masters, usually Hippocrates, Galen, or one of the commentators. Perhaps Galen in some bastard edition was most used. To dissent from any of the opinions expressed in this work was the rankest kind of heresy. The situation was like that of the family in which the father said to the child, "Whatever your mother says is right whether it is or not," and so it was with Galen. Observation and original thinking were simply not done. The career of Roger Bacon and the fate of Servetus were the things offered to the few who were equipped to further the progress of the medical sciences. Latin was the language of science and any attempt to teach in any other language was regarded with the greatest suspicion. Various attempts were made to break the scholastic shackles. Luther translated the Bible into German in 1521 and other translations followed in rapid succession. Bearing these facts in mind, it is not difficult to see what a furor Paracelsus caused when he advocated a return to the study of the phenomena of diseases, to the use of German instead of Latin in his lectures, and when he cast the works of Avicenna into the flames of a student's bonfire, on the Feast Day of St. John, to show that he was done with authority, Basle was startled beyond measure. His career as a teacher in this town did not last long. He might have remained much longer, in spite of the persecution of his antagonists, but for the fact that a wealthy citizen suffering from a painful illness, offered a hundred guldens for any cure. Paracelsus relieved him but with the recovery of his health the patient declined to pay more than six guldens, whereupon Paracelsus brought suit and the court decided against him. What he said about the action of the judges was couched in terms calculated to lead to severe punishment, so taking the advice of his friends he left by night and so ended his career as a university teacher. But in the short space of time he sowed seeds which were later to reap a bountiful harvest. From now on he wandered from place to place. Space prevents following these perigrinations. He stopped here and there to set up an office as a physician or a laboratory for the pursuit of his studies, and while he was successful in practising and must have had a certain amount of financial success, he was, nevertheless, almost always poor.

Toward the end of his life a trip to Vienna placed him in more or less comfortable circumstances and while there he was much honored. He finally retired to Salzburg where he died in September, 1541. Though less than fifty years of age, his struggles and disappointments and long hours of exhausting labor, had given him the appearance of a very old man. He was buried in the church yard of St. Sebastian. Some fifty years later his bones were put in a place against the wall of the church and a couple of centuries afterwards they were moved a second time. The remains of his skeleton were studied by Von Sömmerring, who gave rise to the myth that he had been assassinated, but this was controverted by Aberle who made a number of examinations of the bones, the results of which were published in the work alluded to above. The translation of the Latin inscription in St. Sebastian's church is given by Stoddart as follows:

Here lies buried
PHILIP THEOPHRASTUS
The Famous Doctor of Medicine
Who Cured Wounds, Leprosy, Gout, Dropsy
And Other Incurable Maladies of the Body, with
Wonderful Knowledge and Gave His Goods to be
Divided and Distributed to the Poor.
In the Year 1541 on the 24th Day of September
He exchanged Life for Death.

Paracelsus was a prolific writer and many of his works were printed during his lifetime, but more after his death. He wrote on all manner of topics, theorizing on the nature of things, on chemistry and metallurgy, on philosophy, on life and death, theology, in fact almost the whole range of the knowledge of his time. He did not spare his enemies but speaks of them in no uncertain language. In fact, he may be regarded as a master in vituperation. Along with so many of the men of his time, he believed in astrology. He rejected the old Aristotelian elements, the fire, air, earth, and water; the hot, dry, moist, and cold; and substituted for them mercury, the principle of liquidity and volatility; sulphur, the principle of combustibility; and salt, that principle which is permanent and resists the action of fire. He divided the macrocosm or external universe into three worlds, the visible tangible; the astral or world of heavenly bodies; and the celestial, or the divine and spiritual. The miscrocosm or man, he divides into three corresponding divisions, the visible and tangible; the bones and muscles and so on; the astral, the sensations; and the celestial, the soul.

Stillman gives a short but clear account of the prevalent medical beliefs of the sixteenth century as regards the causes and cures of diseases, using as a basis the work of Troels-Lund. Paracelsus described five active principles which influence the health of man—the stars, poisons, influences in the nature of the individual himself, influences acting through the spirit, and lastly, the will of God acting directly to produce illness as a warning or punishment. All of these were in vogue at the time in which he lived and Paracelsus wrote extensively explaining the various bases of his belief. A quotation or two from Paracelsus will give some idea of his style:

> That you may understand what it is that heals wounds, for without that knowledge you may not readily recognize the remedy, you must know that the nature of the flesh, of the body, the veins, the bones, has in it an innate force (mumia) which heals wounds, thrusts, and such like things. That is to say, the force lying in the bone heals the fracture, the force naturally contained in the flesh heals the flesh. So with every member, it must be understood, each has its healing in itself and thus nature has in every member that which heals the wounded part. Therefore the surgeon should know that it is not he that heals, but the force in the body. If the physician thinks it is he that heals he deceives himself and does not understand his art. But that you may know for what purpose you, the surgeon, exist, learn that it is to provide a shield and protection to nature in the injured part against enemies, so that these external foes may not retard, poison, nor spoil the force of nature, but that it may remain in its vital power and influence by the maintenance of such protection. Therefore he who can protect and take good care of wounds is a good surgeon.
>
> In nature's battle against disease the physician is but the helper, who furnishes nature with weapons, the apothecary is but the smith who forges them. The business of the physician is therefore to give to nature what she needs for her battle. . . . Nature is the physician.

Paracelsus was usually antagonistic to the rest of the profession, and if anyone is interested in this side of him, they will find in the introduction and also in the body of his work entitled "Paragranum," some interesting examples of writing.

Paracelsus did much to further the development of chemistry and the use of chemical drugs in medicine, so much indeed that the advocates of the latter were frequently called by his name. He was the first to describe zinc and he made a number of contributions to chemical and metallurgical processes. Of his work in chemistry, Stillman says:

> The great service of Paracelsus to chemistry was not in any epoch-making discovery nor in any development of theory of permanent value, but in opening a new and great field for chemical activity in the application of chemistry to the preparation of mineral and vegetable remedies. He not only put into use many known chemical substances in his practice, but he advocated insistently and forcefully the necessity of the knowledge of chemistry to the physician, and emphasized the value of experiment as against dependency upon the records of the ancients.

In medicine he did much. His work, "The Greater Surgery," *Grosse Wundartzney*, went through some nineteen editions and was translated into several languages. He gave a good description of hospital gangrene, made numerous observations on syphilis, and is credited with being the first to call attention to the connection between cretinism of the offspring and goiter of the parents. Some of the students of medical history believe that he was the first to recognize hereditary syphilis.

I have not space to go into the many interesting sides of Paracelsus. If the reader is interested he should read Stoddart or Stillman and if possible take a peep into Waite's translation.

Paracelsus was quite a theological writer, but it would take us too far afield to go into this side of his activities. His orthodoxy was questioned after he died, but he apparently always remained in the church and was buried with the faithful.

Ophthalmology in France in 1920.—Writing in *La Médecine*, Cantonnet states that French ophthalmology has now quite caught up with the war interruption, and gives a brief résumé of last year's progress. Under traumatisms he refers to a paper by Frenkel which shows that disinsertion of the iris is always accompanied by subluxation of the lens. In the article by Castelain and Lafargue on tetanus from eye lesions, it is shown that the onset soon follows the injury, while the death rate has been high—17 in 22 cases. When a foreign body soiled with dirt has entered the eye preventive serotherapy must be practised. In the extraction of magnetizable foreign bodies Rollet makes use of an electromagnet, the attractive force of which may reach 1200 kilos under 25 amperes. The current is begun with a minimum and gradually increased. A sensation of pain is felt if the body is magnetizable, so that this resource is partly diagnostic. With additional current-strength the body is seen to lift the iris in its attempts to reach the magnet, and at times there is hemorrhage into the anterior chamber, from which the body may be extracted by corneal incision. The operator cannot make use of magnetizable instruments. Dor prefers a sclerotic to a corneal incision. Naturally there have been many cases of shell fragments in the eye from the effects of warfare. Under operative techniques Kalt, among others, has returned to corneal suture after cataract operations, as less likely to produce notable astigmatism. Barraquer, instead of compressing the globus to assist in the expulsion of cataracts, would use the suction produced by dry cups. The method possesses several distinct advantages. Eperon enucleates the lens in myopia of over 20 dioptrics, selecting the material carefully and operating on one eye only, in subjects under 25.

Lagrange still advocates his method of increasing intraocular tension, especially in hypotensive myopia and retinal detachment. Van Lint takes up an old idea of trephining the ungual bone in order to drain the lacrymal sac into the nasal passages in chronic lacrymation. Others prefer a resection of part of the bone, followed by suture of the nasal mucosa to the lacrymal sac. Several cases of traumatic exophthalmus have been reported cured by tying one, two, or all three carotid arteries of the affected side.

In experimental work it has been possible to cure gonorrheal ophthalmia by injection of an antiserum into the anterior chamber. Roemer has used autoserotherapy with good results (blister fluid) in corneal ulcers and hypopyon. The eye symptoms of botulism have, of course, been published, and this is still more the case with those of epidemic encephalitis. It rarely happens that ocular symptoms are lacking in the latter.

The contents of the Ophthalmological number of the above-mentioned periodical comprise many short articles of interest. Lagrange gives his technique for the operation of fistulation of the bulbus for chronic glaucoma. In Rollet's paper on diagnosis of phlegmon of the orbit it is emphasized that the mischief may have originated in the frontal sinus, which may be subjected to diagnostic puncture. There need be no symptom which points directly to involvement of this sinus. Frenkel describes the so-called anterior traumatic syndrome of the eye which comprises subluxation of the lens with traumatic cataract, disinsertion or laceration of the iris, traumatic mydriasis, etc.

Chevallereau states, under causes of myopia, that no one is ever born myopic and that the affection comes from working with too close a focus, with resulting compression of the media and lengthening of the eyeball. Jeandelize inserts a retention catheter in the lacrymal duct in all wounds involving that portion of the eye. Cantonnet states, of strabismus, that nearly all sufferers from these deviations can be cured by reeducation, provided the affliction is of recent date and slight degree and the victim has equality of vision and refraction in both eyes. Gonin, in his article on ocular headaches, lays special emphasis on the type due to strabismus. Cantonnet discriminates between the eye lesions in the hypertensive and those of the arteriorenal subject. The former are limited to mechanical rupture of blood vessels, while in the latter there may also be retinitis. In regard to post-bellum trachoma, Aubaret of Marseilles states that the influx of subjects from the Orient has increased the number of cases in his locality. Vacher and Denis would always feel the tension of the eyeball before instilling atropine, for the latter is known to precipitate glaucoma in the predisposed.

THE PATHOGENESIS OF DUPUYTREN'S CONTRACTION OF THE PALMAR FASCIA.

BY WILLIAM H. BYFORD, M.D.,

CHICAGO, ILL.

ASSISTANT SURGEON, ST. LUKE'S HOSPITAL.

DUPUYTREN'S contraction was first demonstrated and described by G. Dupuytren in 1831. Since that time the many contributions on the subject have covered most of the aspects of the condition very fully, but the etiology has remained obscure. In the literature, reports of 705 cases have been recorded and an analysis of these, in addition to the 38 cases seen personally, are given in this paper. Unfortunately, most of the data have been given only in a consolidated form and the records of the individual cases are rarely available. Consequently, while these data are valuable in the compilation of statistics, they are of very little value in the investigation of any new theory on the subject.

The palmar fascia, the seat of Dupuytren's contraction, is well described by Keen, who, in his System of Surgery, states that it "is divided into three parts. One lateral part covers the thenar eminence and the other lateral part the hypothenar; these are comparatively thin and extending around the borders of the hand become continuous with the dorsal fascia. The middle and important part of the fascia is thicker, and in part originates from the palmaris longus muscle and in part from the anterior annular ligament. It spreads out like a fan from the wrist downward and divides into four slips, one for each finger. These slips pass down in the median line of each finger and divide at the base of the finger into three smaller processes. The median one of these passes along the palmar surface of the finger, to be inserted into the skin as far down as the pulp of the last phalanx; the two lateral processes surround the tendon sheath and are inserted into the dorsal surface of the first and second phalanges. The anterior surface of the fascia throughout is attached to the skin by small fibrous prolongations. The skin is thus closely adherent throughout." The middle portion may be divided into two layers, the lower of which is composed of transverse fibers and blends with the anterior annular ligament. The upper layer is composed of longitudinal fibers. These longitudinal fibers compose the digital prolongations and are the seat of most of the pathology.

Three varieties of the contraction may be distinguished in which (1) The contraction is limited to the palmar portion of the fascia; (2) the contraction is limited to the digital prolongations of the fascia; (3) both the palmar portion and the digital prolongations are involved. Of these about 35 per cent. are in the first class, about 5 per cent. in the second, and about 60 per cent. in the third.

The appearance of the hand is quite characteristic. Extending from the interthenar concavity to the fingers and often along their palmar surface as far as the first and sometimes the second interphalangeal articulation are raised bands, taut, hard, and closely adherent to the overlying skin. These may extend to as many as all five of the fingers. In the fingers the bands usually lie in the middle of the palmar surface, although in the little finger they may lie to one side. Ordinarily each band is distinct from the others, but that of the ring finger may be connected to either of the adjacent fingers by a narrow fasciculus. The palmar skin is indurated and frequently drawn into dimples or folds running transversely across the palm. Nodules, small shot-like collections of very dense tissue, are frequently present, their usual location being superficial to the bands. At the metacarpophalangeal articulation the skin is puckered into deep furrows by the contraction of the cutaneous attachment of the fascia. In severe cases in which there is marked finger contraction, the skin between the bands is softer than normal from disuse. The contraction results in a flattening of the palmar concavity, the greater flattening being in the longitudinal direction.

The contraction of the fingers varies in degree. In mild cases hyperextension is limited, while in severe the finger is flexed until the tip rests on the palm. The motion in the distal interphalangeal articulation is not often limited, and although the other joints of the fingers may be completely fixed, it is usually quite movable. It may be even hyperextended if the attachment of the fascia passes, as sometimes happens, to the posterior aspect of the last phalanx. The degree of involvement of one finger has no bearing on the involvement of the others. At times one finger, especially the ring, is severely contracted, while the others are not involved at all. Again, there will be a moderate contraction of several of the fingers.

Generally the onset and development of the condition are slow and steady, the first symptom noticed being the increased induration of the palm. Usually the maximum contraction is reached in about a year, although it may come on with comparative suddenness and extreme flexion be

reached in a few weeks. On the other hand, several years may be covered before the maximum is reached. At times a nodule appearing on the palm is the first sign, and this is followed by the development of the band. Rarely do both hands develop together, one precedes the other by a few weeks or months, and the one first affected is the more severe. At times the contraction is intermittent, the hand remaining stationary in the intervals, but this is the exception rather than the rule. Cases have been operated upon before the maximum has been attained and a second contraction followed.

Subjective symptoms are not the rule. When present they are usually a tingling or stinging in the palm. Occasionally they are described as a "drawing" in the palm, extending well up the fingers. One man stated that every few hours he felt a tingling along the bands. Few complain of actual pain.

The diagnosis is not usually difficult. The distinguishing points of Dupuytren's contraction are the cutaneous phenomena and the bands. Paralytic contractions, tendon contractions, and cicatrices are distinguishable by the history and the different physical aspects. The indurated hands of the old show an atrophy rather than an hypertrophy of the fascia. Hammer finger is congenital, due to an abnormal shortness of the lateral ligaments of the affected joints. Cases of congenital Dupuytren's contraction have been reported, but these have not been definitely proven to be true cases. In acquired hammer finger it may not be possible to differentiate the two, although in this condition there is generally the history of an injury and no marked induration of the skin.

Upon dissection these bands are seen to consist of dense fibrous tissue, apparently an hypertrophy of limited portions of the palmar fascia. The fat normally between the fascia and the skin is diminished or gone, and an increase of the fibers connecting the skin to the fascia is present. The bands are distinct, elevated, and tough, and are seen to have origin at the attachment of the palmar fascia to the tendon of the palmaris longus. Their termination may be either at the metacarpophalangeal articulation or well up on the finger, even as far as the distal joint. The tendon sheaths are not involved and the joints are normal. In some of the long-standing cases in which the contraction is very marked there may be some absorption, due probably to disuse.

Microscopically there are variations in the findings of different observers. All agree that there is an increased amount of fibrous tissue and a decreased amount of fat. Chevrot reported a thickened layer of fascia under the skin, sclerotic and fibrous, containing no elastic fibers or connective tissue cells, with a merging of the fascia and the dermis. Anderson found in the progressive cases that "the fibrous strands are intermingled with nuclear proliferation." It is probable that in the progressing cases connective tissue is in the process of formation, while after the arrest of the condition the connective tissue cells disappear and the tissue resumes the characteristics of the palmar fascia.

Statistics vary with regard to the incidence. Anderson in 2,600 adults found it to occur in 1.27 per cent., while in 800 children under 16 years old no cases were found. In 700 examinations Noble Smith found it in 10 per cent., a far higher percentage than the average. Nichols in 1,000 examinations found it in 4 per cent. In a careful examination of 1,000 men at the Cook County Poor Farm, I found 34 cases, or 3.4 per cent. In 106 women there were 3 cases. Averaging these cases, it is present in 3.3 per cent. These statistics are taken in great part from institutions in which the aged predominate. In my own cases the oldest patient was 90, the youngest 31, and the average 70.8 years old. The greatest age at which the condition was acquired was 68, the youngest 25, and the average 47.7 years. There were 5 subjects who did not know the time of onset, either having forgotten or never noticing the condition until their attention was called to it at the time of examination. All of these were very mild.

Men are affected five times as frequently as women. Despite the general opinion to the contrary, men engaged in manual labor are less frequently affected than those who do not engage in manual labor. Keen in 123 cases found 49 performing manual labor and 74 not performing it. Black in 131 cases found 63 laborers and 68 nonlaborers. In the 292 in which this point is taken up, 136, or 46.5 per cent., were laborers and 156, or 53.5 per cent., were not. In the 38 cases personally examined, 24 were laborers and 14 were not. This discrepancy may be attributed to the fact that by far the greater number of inmates of the poor farm are at an age when their physical usefulness is past, while their mentality is but slightly changed. As a consequence the exlaborers predominate. No insane or feeble-minded person was examined, in order that the histories might be as intelligent and truthful as possible.

Of 592 cases, 294 were bilateral and 336 unilateral. My series showed 25 bilateral and 13 unilateral cases. This may be due to the fact that the condition had been present for such a long time; 20.3 years was the average length of time the contraction had been present. In 336 unilateral cases, 225, or 69.9 per cent., the disability was of the right hand, and in 111, or 30.1 per cent., of the left. Of my 13 unilateral cases, 9 were of the right and 4 of the left. Of the 25 bilateral cases, 10 had the right hand involved first, 8 the left, 5 both together, and 2 did not know which hand was first. The average length of priority of the right hand was 5.9 years, of the left hand 4.2 years. The average of one hand before the other, including the 5 cases that came on simultaneously, was 3.8 years.

Of the 38 cases, 10 were palmar, 2 digital, and 26 both digital and palmar. In all, 63 hands were affected, 43, or 69 per cent., involving both palms and fingers; 18, or 28 per cent., being palmar only, and 2, or 3 per cent., digital only; 61 palms and 68 fingers were affected.

Of the 68 fingers: The ring finger was involved 35 times, or in 51.4 per cent.; the little finger was involved 18 times, or in 26.5 per cent.; the middle finger was involved 10 times, or in 14.8 per cent.; the index finger was involved 4 times, or in 1.4 per cent.

Of the 61 hands involved: The ring finger was involved in 57.3 per cent.; the little finger was involved in 29.5 per cent.; the middle finger was involved in 16.4 per cent.; the thumb was involved in 6.5 per cent.; the index finger was involved in 1.7 per cent.

The average number of fingers affected in each hand was 1.14. The most fingers affected in any hand was 5 (1 case).

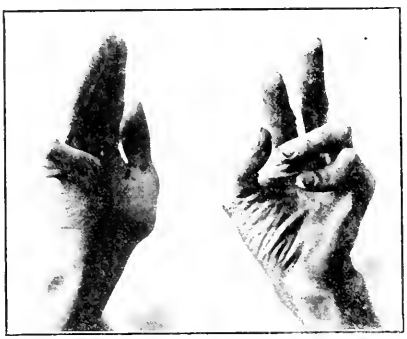
Many theories have been advanced to explain the etiology of Dupuytren's contraction. In 1888 Abbe advanced a neuropathic theory in which a primary injury of the palm, often slight, causes a reflex contraction of the fascia, which in turn sets up another reflex, affecting the other palm sympathetically. Kingsley reported a case cured by two hypnotic seances. It has been attributed to a contraction of the palmaris longus muscle, and to an active low-grade infection. However, no contraction of the palmaris longus has been demonstrated, and neither organisms nor inflammatory tissue have been found. At the present time two theories are in vogue, the first of which is that external agencies are the causative factors. Irritation and trauma from the use of tools, golf sticks, ropes, strains from turning handles, injuries of all kinds and infections of all grades are included in this list. To this theory are several pertinent objections. The larger proportion of people affected are those in whose lives manual labor plays but a small part. Most people are right-handed and so have the right hand exposed to more trauma and stress, yet about 30 per cent. of unilateral cases are found in the left hand. In the bilateral cases about 40 per cent. start in the left hand. The thumb, index and middle fingers are most used and exposed to trauma, yet the affection is least common in these fingers. In the 50 described by Nichols, "In 30 cases there was no history of local irritation, recent or remote." In the 38 cases examined by me, 5 showed a possible etiological factor in a local condition; 4 cases had an injury or strain of one hand from six months to two years before the onset of the contraction. Two of these were bilateral cases, the second hand being affected within two years of the first without sustaining an injury. Of these, the second hand in one instance showed a more severe contraction than the first. The fifth case had had the little finger amputated for "blood poisoning," and nine months later the contraction developed in the ring finger of the same hand. A sixth case was hit on the knuckle by a baseball, but no relationship could be established between the injury and the contraction. Undoubtedly many other minor injuries had been sustained, but of so mild a character as to leave no impression on the patient. The injured cases were 13.4 per cent., too small a percentage for a probable etiology.

The other theory and the one held by most extensive investigators, among them Keen and Black, is that the contraction is due to a constitutional condition. Except for 23 cases associated with rheumatism, which will be discussed later, only 7 cases had constitutional disease. Of these one was associated with diabetes, one with syphilis, one with myocarditis, one with endocarditis, and one with attacks of recurring tonsillitis. One had had a cholecystectomy 10 years before and the other had had an amputation of the right foot and one-half the right leg 8 years previously for a tuberculous osteomyelitis of the tibia of several

years' standing. An eighth case had been blind since early youth. Teschemacher found 33 cases in 213 diabetics. Excepting rheumatism, this is the only condition found with any frequency.

Unfortunately, most of the literature gives no complete tabulation of the previous or concurrent diseases, and very few histories are set down at length. Nichols, however, gives a complete tabulation. A very illuminating statement is that, "In 42 of the cases (total 50) there was a history of rheumatism, in at least half of which the rheumatic symptoms were only slight and occasional, the other half had rheumatic attacks of all degrees of severity." A few lines quoted from one of his histories are interesting. "About the middle of January, 1896, he was seized with a severe attack of acute rheumatism, during which various joints were affected and a stiffening of his neck developed. During this attack a marked fascia contraction developed in both hands, the left preceding the right by two or three weeks." Again, to quote from one of his histories, "Concurrently with the appearance of this rheumatoid attack a marked contraction of the fascia of the right palm



Case No. 8, showing marked contraction of palms and three lesser fingers of both hands with hyperextension of the distal phalanx of the left little finger.

developed, reaching its maximum in the course of about two months." Of the 23 cases of my own associated with rheumatism, 20 cases knew the time of onset of the contraction. In 8 the rheumatism came on nine months to 28 years, with an average of 11.3 years after the contraction. Twelve cases had rheumatism before the contraction, from 1 to 55 years, with an average of 14.8 years. Of the latter, 3 developed the contraction during an attack of rheumatism; in 1 case the contraction increased during each attack, remaining stationary in the intervals. Of the 3 cases that did not know the time of onset of the contraction, one had had rheumatism for 3 years, one for 5 years and one for 20 years. No cases were considered in the above tabulation who had not had a definite and clear-cut attack. Many of the cases who are considered to have had their attacks after the development of the contraction had had vague attacks before. In Nichols' cases the two conditions were associated in 84 per cent. and in mine in 60 per cent. An interesting observation was made by Girdwood.

"The patient, a man of about 40 years of age had had asthma and bronchitis for over 15 years to my knowledge . . . on account of the expiratory dyspnea, and he has to bring all his external muscles of respiration into play. In order to do this he requires a fixed point to work from, which he gets by pressing his hands firmly on the bed. This pressure on the hands has caused the absorption of the palmar fat and the subsequent adhesion of the skin to the fascia."

In this two possible sources of the contraction are revealed, a local and a constitutional.

A patient from my private practice first seen about a year ago, had a severe contraction of both palms, ring and little fingers and a beginning contraction of both middle fingers. The condition had been progressing steadily for about two years. Subjective symptoms were present, consisting of tingling and drawing in the palms and affected fingers, lasting for a few seconds and occurring every 4-5 hours. Physical examination showed the above contraction of the hands and a similar condition of both feet. He also had a postoperative hernia following a cholecystectomy, and an almost useless set of teeth. He had marked pyorrhea and several sinuses from alveolar abscesses. He was advised to have the abcessed teeth removed, their sockets opened up and curetted out, and the other teeth thoroughly cleaned. He complied with the above advice except that he had the abscessed teeth extracted instead of surgically removed. Within two weeks the subjective symptoms disappeared and the contraction remained stationary for six months, at the expiration of which time he returned, complaining that the tingling and drawing had reappeared and that he had noticed an increase of the contraction. A second examination showed a return of the pus and tartar on his teeth. X-ray films showed two more teeth abscessed and a suspicious spot at the site of one of his teeth that had been previously extracted. The two teeth were surgically removed, the granuloma curetted out, the left antrum of Highmore drained through one of the tooth cavities that opened into it, and since that time he has been free from symptoms.

The physical examination of the cases here reported showed them to have about the same physical defects as other people of their age and occupation. However, one very marked condition was noted, the almost universal disease of their teeth. In 5 instances all teeth were gone, in one spontaneously starting as a child, in one all teeth having been extracted for toothache between the ages of 12 and 62, and 2 having had all extracted for toothache when middle-aged. Eleven showed 8 or less teeth, in every instance being markedly decayed. Three cases showed active alveolar abscesses with sinuses. Twenty-one showed pyorrhea, in each instance severe. Twenty had teeth fall out spontaneously, the greatest number being 32 and the least 2. Thirty-six had had teeth extracted for toothache, the most being 32 and the least 1. Twenty-nine showed markedly decayed teeth, 19 had decayed teeth and pyorrhea together. Twelve complained of having had severe toothache for ten years or more before the onset of the contraction. Five showed teeth in fair condition, of these 4 had had rheumatism, 1 with recurrent attacks of sore throat, 3 with no etiological factor determinable. In 2 of the latter the contraction came on during an attack of rheumatism.

Rheumatism is now quite generally considered to be due to a focal infection. The association of rheumatism with Dupuytren's contraction in from 60-84 per cent. of cases makes it evident that a focal infection is at least quite commonly present in the latter condition. In 34 cases dis-

eased teeth were demonstrated. In 1 recurrent tonsillitis with rheumatism, and in 2 rheumatism without demonstrable etiology, in which, however, the rheumatism and the onset of the contraction were concurrent, were present. A source of infection was thus present in 97.3 per cent. It is evident that Dupuytren's contraction is frequently associated with rheumatism, and probably, like rheumatism, is the result of bacterial action at some remote part of the body. The most common location of this focal infection is in the teeth. In only one case was there opportunity to put this theory into practice. That case, described above, responded very well.

The treatment is purely surgical. X-ray, fibrolysin, ionization, and the iodides have all been tried without result. Dupuytren dissected out the fascia and involved skin, allowing the wound to heal by granulation. Adams was an exponent of subcutaneous division of the bands, followed by splinting, for a long period of time. Aseptic surgery has caused this method to be abandoned, and the open operation with dissection of the palmar fascia from the skin and from the underlying structures is generally performed. This is usually followed by splints, constantly in application for one month, intermittently for another month, and at night for from six to eight months.

Hutchinson in his Hunterian address in 1917 offered a somewhat more complicated but better treatment. He believes that the long-continued splinting results in frequent stiff joints and recurrence of the contraction. He makes a palmar incision and dissects out the fascia. If the case is recent, no further surgical procedure is necessary, and the fingers after a few days, a week at the most, are moved passively and soon actively. Except during the first few days, no splints are used. Many times, especially in long-standing cases, the joints (particularly the proximal interphalangeal) have become fixed from a contraction of the lateral ligaments, and, after the fascia has been removed, the finger still cannot be extended. He makes an incision over the dorsal surface of the proximal phalanx, divides the extensor tendon, exposes the head of the proximal phalanx, cuts through the neck and dissects out the head. The extensor tendon is then shortened, sutured, and the wound closed. If there is difficulty in closing the wound on the palmar surface of the finger, he uses a flap from the side of the finger. The aftertreatment is the same as in the recent cases.

He works through a palmar incision parallel to the bands. The Y-shaped and V-shaped incisions give a good exposure, but leave an extensive scar of the palms that is often a source of great inconvenience. Gill, in 1919, used a transverse incision conforming to the distal fold of the palm. The scar from this gives very little trouble.

In operating on these hands the surgeon must be sure that the contraction is stationary. That long splinting would cause a stiffness of the joints is not improbable, but that it would cause a recurrence of the contraction does not seem reasonable. To insure against a second hypertrophy and contraction of the fascia, a thorough examination should be made and all sources of infection removed. A careful measurement of the contraction compared with a second measurement six months later will indicate whether or not the condition has become stationary. If it has been stationary for six months after the removal of all infected tissues, the probability of a second contraction is small.

Conclusions:

1. Dupuytren's contraction is frequently associated with and closely allied to rheumatism.
2. It is probably due to bacterial action at some point other than the palmar fascia.
3. The most common site of this infection is in the teeth.
4. All foci of infection should be removed to prevent progression of the contraction.
5. A period of six months should elapse between the removal of these foci and the treatment of the contraction itself.

BLUE ISLAND, ILL.

POST-SOMATIC PSYCHOSIS.*

BY B. LEMCHEN, M.D.,
CHICAGO, ILL.
PHYSICIAN TO THE CHICAGO STATE HOSPITAL

UNDER this heading I would include those psychoses that develop after a physical ailment from which ailment the patient has recovered, such as infectious disease, confinement, trauma, in discharged soldiers, or in chronic alcoholics after they have stopped using alcohol. The influenza epidemic, the war, and prohibition have given a good opportunity to study those psychoses more closely.

I will first describe a few of the cases that were received at the Chicago State Hospital during the last few years and will discuss them afterwards.

CASE I.—Margaret G., American, 21 years old, single, admitted Nov. 2, 1918. Family and personal history negative. On Sept. 23, 1918, she was taken with influenza, was sick for two and one-half weeks, when she commenced to improve and in a few days was up and about. Five days after she recovered mental symptoms developed. She began to talk irrationally, would laugh and cry, imagined she was talking to different kinds of people, that she was in France; thought she heard

*Read before the Irving Park branch, Chicago Medical Society, February 21, 1921.

her parents who were dead and her brother who was killed in France. When admitted she was entirely clouded in mind and restless. Five days after she was admitted she gave her name correctly, thought that she was in Cook County Hospital, that it was May 26, but couldn't give the year. She was asked why she came here. She answered to be born. She was asked if she ever heard of Dunning (the previous name of the Chicago State Hospital). She replied, "Why should I be in Dunning? It is a nice place to be in when there is nothing wrong with my mind and I have no goiter." She told the examiner that she was born in France on May 26, that she was 16 years old. Her father was 29 and her mother 19 years old. Her general knowledge was tested. (Patient had been two years in college.) She could name the President and the Mayor of Chicago but not the Governor of Illinois. She couldn't name any of the large cities in the United States nor could she give the boundaries of the United States. She was asked about the war and she said it began in Ireland and is now in France. Then she talked in a rambling manner that couldn't be followed. She wouldn't state whether she was hallucinating or not. Her stream resembled those of a dementia precox subject. Her physical examination was negative. From the beginning she became worse, her stream became more rambling; then she commenced to improve, and finally recovered. On Nov. 25 she told the examiner after asking her name, "Let me see my lost whiskey. What else do I have to know? Can you fix my tooth? Are you a dentist? I was sick with childbirth pain. I have a goiter, the church is Rom, seven sons." She was singing and restless but not violent. She admitted hearing voices and was disoriented in all spheres. On Nov. 27 she recognized the place as the Chicago State Hospital, otherwise her stream was still so rambling that it couldn't be followed. On Jan. 6, 1919, she gave the name of the place and told the examiner she came to the hospital because she was sick; then she began to ramble about glass and teeth, and could not give the date. However, she knew that the examiner examined her before. She told him that voices told her she had seventeen brothers, etc. Her behavior varied; some days she would behave well, while on others she would be restless, tear her clothes, break dishes, and use profane language. On March 19, 1919, she commenced to improve gradually and on March 29 she was oriented in all spheres, was quiet, self-possessed. However, she was shy and it was hard to get answers from her, but when she did answer it was to the point. She also gained in weight. The improvement was constant and on April 7 she was paroled in the care of her brother and apparently has recovered.

Case II.—Laura B., colored, American, 29 years old. Admitted Nov. 21, 1918. Family and personal history negative, except she was a moderate user of alcohol. She had influenza, from which she recovered, and was well for four weeks when mental symptoms developed. A week before she was admitted at the Chicago State Hospital she ran away from home, and went to the police station, and asked the police where she was. The police, recognizing that there was something wrong with her mind, took her to the Psychopathic Hospital. The reports from the Psychopathic Hospital stated that while there she was disoriented in all spheres. Had visual and auditory hallucinosis, ideas of poisoning, and threatened the psysician. When admitted to the Chicago State Hospital she could give her name but not the name of the place. However, she knew it was a hospital and said she came on account of influenza. The date she gave as Monday, April 26 (it was Saturday, Nov. 23). She was asked if she had heard of Dunning. She replied: "Is this Dunning? Do you think I will ever go home?" She began to cry and when asked why she cried said it was because she was in an asylum. She stated she had been in the hospital a week (two days was correct). Her personal identification she gave as follows: She was born in 1878 and is 29 years old; she married three times in two years, had three children, one died at 20, one at 16, and one at 15 years. She couldn't correct any of the discrepancies. Her general knowledge was also poor. Physically, she was well nourished. Examination of chest and abdomen was negative. Neurological examination. Pupils reacted sluggishly to light, speech defective, deep reflexes exaggerated, there were fine tremors of the tongue and outstretched hands. Her mental and physical findings were suggestive of paresis. However, the spinal fluid was entirely negative—no cells, no globulin and the Wassermann was also negative both in the fluid and blood. The patient remained in about the same condition until the middle of December, when she commenced to improve, and in the first part of January she became oriented in all spheres. She also knew the length of time she was in the hospital, how she came out to the hospital, and what was done for her when she arrived at the hospital. She denied all forms of hallucinosis, knew that she was sick, had good insight. Her general knowledge was also as good as could be expected from a woman of her station. The physical findings also disappeared and she was paroled in care of her husband on January 8, 1919, apparently recovered.

Case III.—Luey T., Armenian, age 21, married three years, had two children. Admitted January 16, 1919. Family and personal history negative. Four weeks before she was admitted she had influenza and was sick for a week. After she recovered her child took sick with influenza and died. A week after her child died mental symptoms developed. The husband stated she commenced to talk queerly, changed from subject to subject, ran about the house, and seemed to be afraid. However, she knew everyone. When admitted to the Chicago State Hospital she gave her name correctly. Told the examiner she knew where she was and that she could speak English. However, she spoke mostly Armenian, which the examiner did not understand and so could not follow her stream. She was very restless, running around the ward; her mood was changeable, would laugh, then cry. At times she showed considerable fear, at other times was playful. She would look at the physician, smile, shake her head, wink with her eyes, then suddenly without any reason would cry. When first admitted she refused food and the physician had to spoon feed her; then she commenced to take water from the nurses, and later milk, then also solid food. She talked mostly in Armenian and the physician couldn't follow her stream. However, the second day after she was admitted her husband, who is also an Armenian, visited her and he told the examiner that at first she knew him but later she talked so that he himself could not understand what she was saying. She remained in about the same condition until February 3, when she commenced to improve, and would answer questions intelligently for a few minutes at a time. She told the examiner that she could not talk English well, that she was hearing voices telling her that she was no good, was restless and at times would cry at the top of her voice. She also improved physically. On March 7 she was happy, laughed, ran around the ward, always doing something, was talkative but spoke only Armenian. On March 12 she was restless, noisy, and at times violent, would not keep her clothes on. April 28 she could give her name and the name of her husband but she didn't know where she was nor how she came to the hospital. She told the examiner that she had the influenza before she came to the hospital and that she did not like the hospital but wanted to go home to her baby; apparently she did not remember that her baby was dead. She heard no more voices, but was still restless; happy, but destructive to her clothing. From that day on she continuously improved and on May 25 her husband, who was visiting her quite often and talked to her in Armenian, said she spoke normally, and as she had acted normally for several weeks, she was paroled in her husband's care apparently recovered.

Case IV.—Elsie H., American, age 31 years. Mother of a child 10 years old. Admitted March 6, 1919. Family and personal history negative. On January 10, 1919, she gave birth to a child, and was all right until five weeks after delivery, when suddenly, after she had had supper, she complained of being tired Then she cried and thought she was going to die and according to her husband, who gave the history, she raved all night. She got better the next day, but got worse the same afternoon, when she raved, sang, cried, laughed, etc. When admitted to the Chicago State

Hospital she was very restless, resistant, and apparently mentally clouded. It took several nurses to give her a bath. She pounded with her fist on the wall. No sensible information could be gotten from her. She only gave her first name correctly, and occasionally would say "one cent," "orange" but would not explain what she meant. On March 10, when the examiner asked her her name, she answered: "Take me home; this is a hospital, and I suppose I am sick." Then she asked the examiner where her clothes were. She told the examiner that she heard voices but they told her nothing. She asked the examiner whether he was Herman L. (which was afterward found to be her father's name, and the examiner bears no resemblance to him). She asked the examiner whether he died and came to life again; asked if uncle was living. She told the examiner she liked it here, but was not going to stay; was going to 2113 G Street, and gave her name correctly. In her behavior she was violent and restless; would run around the ward, and was still confused, but recognized that she was at a hospital and not at her home. On March 3 she told the examiner that she was tired of this place: the people here were mean to her, and she had nothing to eat the whole day. She cried and said she wanted to go to her children. She was sick and getting sicker; insisted that the physician was Herman L. On March 27 she refused to talk to the physician. When the examiner tried to speak to her she turned her head away from him. On the same day she attacked her husband, who was visiting her, broke a window at the hospital, and cut her forearm. She remained in the same condition till June 27, when she commenced to clear up. She told the physician that she remembered coming out to the hospital in a trolley, but couldn't remember on what date; thought she was at the hospital about three months. She remembered some of the things that had happened during her stay there. She had a nervous breakdown, and it seemed to her like a dream. She remembered seeing and hearing many different things. Saw soldiers and camels marching; thought she went through a tunnel in an airplane; thought she was dead and buried; the physician looked to her like her father-in-law. At first she thought what she saw and heard were real, but now she knew that it was all an imagination. She had good insight in her condition. She could give no reason why she should have had a nervous breakdown as she lived a happy life. Her improvement was steady, and she was finally paroled in her husband's care on June 30, 1919. She was seen several times afterward and had made a complete recovery.

CASE V.—Mary B., female, American; colored; aged 30 years. Was married twice. Has one child 12 years old. Her father was drowned accidentally, otherwise her family and personal history was negative. Admitted February 6, 1919. The patient was well till three months ago, when she pricked her hand with a safety pin. It became infected, and the whole arm became swollen. She was in bed, and a physician treated her every day until the hand got well. Then she became delirious. The physician told her husband that she must stay in bed, but she would not stay in bed, and became unmanageable. She refused food at times. She would say they were giving her poison. She would talk all day and night, but no one could understand what she was saying. Finally the physician advised them to send her to the Psychopathic Hospital. The Psychopathic Hospital records state that after her admission over there she developed a myo- and endocarditis, and her condition was very grave. When admitted to the Chicago State Hospital she was in a confused state. She was asked her name and answered: "Yesterday I was so frightened that I told you my name was B., but it is not, as I married the other fellow. Just call me Mary, and you will make no mistake." Then she pointed toward the door, and said: "Did you see the accident of my mother, father, and grandmother? It happened right outside here. They got killed." She cried, and said: "Papa was afraid of the fish." When asked for an explanation of her statement, she said fish that swim in water. She pointed toward the wall, and asked: "Who does the shooting?" Then she looked toward the ceiling, smiled, and said she saw so many lights. (The electric lights were on that day.) She looked around, and said: "This place is nice and clean; is this a hospital?" She was asked whether she was sick and she answered, "My mind feels funny." She was asked whether she thought that she was insane and she answered, "I should say not." She turned her head backward and showed considerable fear. When asked what frightened her, she answered that there were so many women in white sheets coming up, and they frightened her. She could tell how long she had been at the hospital, but could not give the date. She was asked if she knew what month it was, and replied, "Christmas I came in, and this is May or March." She told the physician that she was first in the county hospital, on account of an infection of her left hand which spread to her arm. While at the county hospital she saw lots of spooks walking around in white sheets and heard cutting of wires and big bombs that were thrown there at night. Sometimes she could not remember everything that happened to her while there. She said that this morning, when ready to go on the boat, some one walked with her. She looked about the ward and said, "This doesn't look like the place they took me in yesterday." She suddenly became frightened and said she could hear different voices. "Mrs. Williams says she will shoot me and Mr. Kelly asserts that I did not respect the German flag." She gave her personal identification as follows: She was born in Arkansas; is 27 years old; reached the seventeenth grade at 15 years of age; married at 16 years. Her husband is in the lake, down here (pointing toward the pond on the hospital grounds). She has a girl, 14 years old. She had more, but only one came to time. She is a Methodist. Her father, mother, and grandmother got drowned. (Only her father was drowned.) Her general knowledge was tested. She could name the President, but not the Governor of Illinois, or the Mayor of Chicago. She could name two of the large cities in the United States and two of the great lakes. She was asked about the recent war, and she stated the Germans and Americans were fighting, and most all the other countries. "They say the Germans lost, but they are still fighting." She was asked of the previous wars this country had, and she answered, "We were fighting Spain and a dozen other wars. Abraham Lincoln freed the slaves. George Washington was a general, and he fought against the North." She was very poor in figuring. Physical examination revealed: Head negative. Heart rapid, 120 per minute; sounds weak, but no murmurs. Lungs negative. Abdomen negative. Neurological examination: Pupils did not react to light; there was considerable tremor of the tongue and outstretched hands; gait was ataxic, and knee jerks exaggerated. Spinal fluid was negative; no cells; negative chemical tests, and a negative Wassermann. Patient remained partially clouded for a long time. On March 25, 1919, she had an epileptic seizure, and after the seizure she became still more clouded, lying in bed for three days in a stuporous condition. On the fourth day she commenced to talk, and asked why people were saying things about her, and why they hacked when she was eating her food. She gradually improved physically, but not mentally, except she became somewhat clearer. She tried to get out of the ward, watching the door; would strike the other patients without apparent cause; became restive and negativistic. She thought she was pregnant. As an example of her stream, on June 17, 1919, she said: "My mind is sick; not strong. Sometimes I feel all right, while at others I do not. It seems that something is moving in my abdomen. I came here about Christmas. Two children; a girl 12 years. This is the middle of June, 1919, and something. I was feeble when I was on 19 (the name of the receiving ward). I cry when I remember the baths. Do you know what I know?" etc. She continued in about the same condition until the beginning of the year 1920, when she commenced to improve mentally, and on February 23, 1920, she was paroled in care of her husband, when she was clear, oriented, with good insight, and on May 22, 1920, she was discharged as recovered.

CASE VI.—Emma S., Norwegian, 43 years old; married three years; no children. Admitted March 26, 1920. Family and personal history negative. Her husband stated that the patient was well up to a

couple of months before she was admitted, when she commenced to repeat sentences over and over again; would talk about moving pictures; would dress in men's clothing, and walk on the streets; would get out of the house in the middle of the night, and walk on the snow for hours at a time. Would pull down the shades and hang newspapers over the windows; would hang a sheet over the door, saying she was doing it because she was watched and spied upon. At times she would rave, saying she was going on the stage to become an actress and marry a prominent man. The records from the Psychopathic Hospital state that while there her orientation and memory were good; general information and calculation fair; was restless and indifferent; had many mannerisms and speech disturbances. She said she was brought there by her husband. Admitted auditory hallucinosis. When examined here she was found to be clear and oriented; gave her personal identification correctly. Told the examiner that before her marriage she worked as a domestic and led a promiscuous sexual life. However, she never had any venereal disease. She was nervous since 1913; could not sleep, and for that reason contracted the drinking habit. She has been drunk on many occasions; would consume as much as a pint of whiskey a day. However, she stopped drinking about a year ago, and has not drunk any since. She married three years ago, and her married life was a happy one. Since last winter she has been hearing voices in Swedish and English. She never was able to identify whose voices they were. The voices told her that she was a bad woman; she was foul, immoral, a German spy, and her nephew who was in the army would have to die to atone for all this; that people would be killed on account of her, etc., which made life miserable for her. However, with all this she was not depressed emotionally, but rather indifferent. Her consciousness was clear and was well oriented. Her general knowledge was as good as could be expected from a women of her station. Physically her knee jerks were exaggerated. No evidence of peripheral neuritis. Her pupils were unequal, the left smaller than the right, and fixed; she had had an injury to her left eye when she was 18 years old. Spinal fluid was entirely negative; no cells; chemical and Wassermann tests were negative. She gradually improved, the voices became less frequent, and finally disappeared by May 6, at which time she was given a ground parole. She developed insight, and was paroled in care of her husband on August 2, 1920, as recovered.

CASE VII.—John W., American, 39 years old; single. Admitted June 8, 1920. Family and personal history negative. Patient reached the eighth grade in school, was a stove repairer. He was drinking heavily for eight or ten years. His sister, who gave his history, had often seen him intoxicated, but for the last two years only occasionally. This was the first attack of mental trouble the patient had ever had, the records from the Psychopathic Hospital stated. While there orientation, memory, general knowledge and information were good. He was restless and happy. Stated he heard ringing in his ears; felt a paralytic stroke through his whole body; thought something was wrong with his blood; thought the people next door to him were after him, and threatened to get him on account of his money. While here the patient stated he was drinking heavily up to two years ago, when he stopped. Dated back his present trouble to three weeks before his admission, when he rented a room and told the landlady that he had a baseball lottery ticket and he had a good chance of winning, and he thinks now that a woman that had a room next to his must have heard it. The next evening he noticed two men and two women sitting in that woman's room with the light turned off. As he passed the room he heard them talking, and thought he heard his name called. As he returned to his room he heard one of those women ask him why he did not spend some of his money, and why he did not ask them into his room, and made indecent remarks about him. He thought he had better get out of such a place, so he dressed, went out on the street, took a car, and rode a while. Then he went to one of the parks and remained until the next morning. The next day he told the landlady that he would move by the end of the week. He went down town, rented a room in a hotel, went back to his room to get his belongings, and told the landlady why he was moving, and he thinks the other woman must have overheard it, as he heard her say she would get him yet, even if she had to follow him all over the world, and that he would have no more rest. He believes now that the woman must have been connected with a bunch of crooks or crooked policemen. He worked during the day, and would go fishing in the evening. One evening, while sitting on the pier, two men sat down on one side of him and three men on the other side, and a short distance away was an automobile in which he recognized the same woman sitting with two other men. The two men came over and talked with the two men that were sitting near him, and it seemed they were talking about him, as they were looking in his direction. He became frightened, got up to get a street car; then those men got in their automobile, and when he arrived near a car they were only a short distance from him, and two of the men got out of the automobile. He took the first car he could get and rode toward town, transferring several times, when he left the car and went to look for a policeman. When he met one he told him his troubles, and the policeman advised him to go to the station and swear out a warrant against those men. After arriving at the station he was afraid of leaving the place, and asked the police to let him stay there over night, which they did. The next morning the police would not let him out, telling him they would have to find that woman; that it would be too dangerous for him to be outside, and he was taken to the Psychopathic Hospital, and from there he was sent out here. Now he thinks that the police were in league with that woman, and were carrying out her instructions. Mentally he was clear, oriented; his general knowledge was good. He was well behaved, and took good care of his person and dress. Physical examination was negative, so were the laboratory tests—no cells. Chemical and Wassermann tests negative. From the time of his examination he gradually improved, taking an interest in the activities of the institution, and was paroled in care of his brother-in-law on September 9, 1920. He was seen several times after his parole, and apparently has recovered with good insight.

CASE VIII.—William S., American, 49 years, married. Admitted June 3, 1920. Family and personal history negative. Present trouble as given by his wife: Patient was well up till April 1, 1920, at which time he was hurt and taken to the County Hospital where he was unconscious for six days. Was operated upon at the County Hospital for a skull fracture. Two weeks later his right eye became inflamed. He was taken home but was going to the hospital for dressings. Then he developed expansive ideas. He thought he was a United States marshal, a police officer, said he was in an airplane, etc., and was taken to the Psychopathic Hospital. The records from the County Hospital state that he was admitted there April 1, 1920, suffering from a skull fracture, otitis media, and mastoiditis. The cause of the injury was unknown. He left the County Hospital May 21, 1920, in apparently good condition. The records from the Psychopathic Hospital state: Physical, right side facial paralysis, recent mastoid operation and panophthalmitis of right eye. Mental, orientation and memory good. Retention and calculation fair. General information and judgment good. Stream of talk. Patient is attentive, cooperative, and talkative. States he received a head injury two weeks ago and was taken to the County Hospital where he remained seven weeks in Ward 21. Left there last Friday, and he was also in Ward 4. When he was admitted to the Chicago State Hospital he was quiet, clear, showed no confusion. The only thing peculiar about him was his circumstantiality. He told the examiner that he left a store at 4:20 and got on a street car and rode to Thirty-fifth and Iron Streets; he was waiting there for another car on the north side of the street. The sidewalk was crowded so he walked across the tracks by the southbound street car. He was standing with his back to the car on the sidewalk; an automobile came along, turned around; the car skidded into the sidewalk. The door of the automobile opened, and struck the patient, knocking him across the walk, against a building, and he was knocked unconscious.

That is what people told him, for he was hurt so bad that he couldn't remember anything. When he came to himself he was in the County Hospital. He told the examiner, when he came to himself, he felt elegant, he recovered the sight in his right eye which became totally blind. (He was blind in the right eye.) He also told the examiner that he was a United States Marshall, a special policeman. Four months ago he went to Grand Park, where he met a friend who took him in an airplane, etc. He could give his personal identification correctly, his general knowledge was good, and he denied hallucinosis. He gradually improved, developed insight, and was paroled in his wife's care on July 20, 1920, in fairly good condition. He visited the hospital a few weeks after his parole and seemed to be in good condition. On September 20, 1920, he was returned to the hospital from his home in an apprehensive state; he was afraid something might happen to him, and was agitated; however, he was clear and well behaved. On October 10 he had a convulsion involving one-half of his body and died the same day. An autopsy was performed by the coroner's physician, who found that he had an old hemorrhage on the right cortex with a septic meningitis.

CASE IX.—Abraham L., Russian Hebrew, aged 29 years, in United States four years. Was admitted to the Elgin State Hospital November 2, 1917. Their records state that his family and personal history were negative. According to his aunt, who gave the information, in July, 1917, he was riding a bicycle to work when he was struck by an automobile, receiving a head injury, and was taken to a hospital, where he remained three weeks. For two weeks he did not recognize anyone and since then he had not been in a normal mental state. He worked very little, everything got mixed up in his head, and they would not keep him in any place. Recently he imagined that his wife, who is in the old country, is here. When he saw a woman with a baby carriage passing he imagined it was his wife and wanted to go to her. Talked about a man wanting to kill him because he worked so fast and accomplished so much in the shop. Thought he knew every one he saw. Was talking and walking around the house all the time. Cleanly in habits. Not violent. Memory good. Stated many people are watching him. An investigation by the Bureau of Personal Service brought out the following facts: He was injured on July 13, 1916, was taken to the St. Luke's Hospital, where he stayed three weeks. After leaving the hospital he was at his aunt's home for two months and was able to work the following six months. A letter from St. Luke's Hospital says he was received there on July 13 and remained until August 5. He had a basal skull fracture and was discharged as improved. From notes taken in the Elgin State Hospital we learn that when he was admitted there he was dull and uninterested, frequently declining to answer, telling the examiner that he (the examiner) knew better than the patient. Showed a letter in Yiddish that he had written to his wife and when the examiner asked him what it contained he stated he wrote his wife that he was crazy. He was clear and oriented and the examiner could not demonstrate hallucinosis nor delusions. A note on February 6, 1918, states that he was transferred to the male infirmary very untidy and destructive. On February 12 his mind seemed to have so deteriorated that he was unable to answer any questions. He seemed completely demented. He would sit around the ward as if in a stupor, but at times was very destructive of his clothing. There was no organic physical defect, but the physician believed he was failing physically. On February 26 the Wassermann test was positive. He was having convulsions. On March 22 he was very restless and noisy, and threw a tray of dishes at another patient. On March 25 he had a hemorrhage from his bowels. By April 3 he had quieted down considerably. A large abscess on the buttocks which contained a large amount of yellow pus was opened. On April 30 there was no change. He usually lies in bed with his bedclothes over his head and is either quiet or groaning. Occasionally, especially at night, he gets up and does impulsive acts such as breaking windows or flower pots. He also destroys his bedclothes. His physical condition is steadily getting worse. On August 31 a note of the Chicago State Hospital states that the patient was a transfer case from Elgin State Hospital, being in very poor physical condition; he had been restless and untidy. Had a marked diarrhea and was greatly emaciated. He was sent to the hospital ward, where he gradually improved mentally and physically, beginning to take an interest in his surroundings. Worked first on the wards, then at the employees' dining-room, and was finally paroled to his wife who came to this country, on August 15, 1920, greatly improved, and as far as we have heard he is getting along well.

CASE X.—Samuel H., American, colored, 30 years old, married. Admitted to the Chicago State Hospital on February 11, 1920. Family and personal history negative. Present trouble, as given by his wife: He was drafted in the United States Army on August 1, 1918. He went to France but never was in a battle. Was mustered out July 25, 1919. After leaving the army he was getting along all right until two weeks before his commitment, when he complained of backache; then he stopped working and talked at random. Said someone had put a spell on him six years ago and it was to take effect this year. Said he was losing his mind. He went to a doctor, who prescribed for him. He took one dose of the medicine, then refused to take any more, saying the next dose would kill him. He thought they wanted to kill him so they could take his wife and wealth from him. Tuesday night before he was committed he could not sleep and was continuously getting up looking out the window. He said someone was trying to get into the house. The next morning when the door bell rang he went to the door with his revolver in his hand. Then he went into an epileptic status and four or five fits. The wife stated that this was the first time he ever had fits. The next Thursday he had fits all day. He took the ironing board, put it on two chairs, and laid himself on it as he were dead. Said if anyone talked to him he would lose his soul. Sprinkled salt over the floor, saying this was to keep out the man that wanted to kill him. The records from the Psychopathic Hospital state that the physical examination was negative. Orientation was fair. Memory for past and present events good. Retention good. General information, calculation, and judgment poor. Emotional attitude apprehensive. Stream of talk. Patient talks continuously about hallucinations and prays to be saved. When admitted to the Chicago State Hospital he was oriented and clear, except for a short period of syncope. When an attempt was made to puncture him he became apprehensive, unclear, and almost fainted. He became depressed and said, "A heap of time I feel I have no friends and everybody is against me, then again I feel like I have plenty of friends and can get along all right." He said a fortune-teller frightened him by foretelling that he would lose his mind and would work so hard that his heart would fail. Then he said when he left here he would seek an easier job, and he has no longer that sad feeling. When the examiner mentioned to him some of the facts given in the history, he said he must have been crazy but he was not crazy now. He had a partial amnesia for things that happened to him prior to his commitment. His physical examination and laboratory tests were all negative. During the time he was in the Chicago State Hospital he was not observed in any epileptic attack. He gradually improved during his stay there; he lost his anxiety state, became clear again, took an interest in his surroundings, and was paroled to his wife on July 20, 1920. We learned since that that patient is working, getting along well, and apparently has recovered.

CASE XI.—Roy M., American, colored, single, 20 years old. Family and personal history negative. Present trouble: According to his aunt, who gave the history, the patient went to the army a year and a half ago. Was sent to France, where he spent several months. Returned to this country April 13 and as far as his aunt observed him he was well but rather restless. Shortly after she noticed he was not sleeping well. He would be up at night walking about the room. When she asked him what was the trouble he said he was on guard duty. One time he went out, taking fifty or sixty dollars with him, returning in a few hours telling his aunt he gave all his money away. Everyone he met seemed in need. He seemed happy.

He would start to do some work but would never finish it, starting on something else. He was not irritable nor did he fight. He would go into other roomers' rooms and help himself to their ties, collars, or other articles, which he would wear in the house in the presence of the owners. When spoken to about it he would return the articles without any argument. The records from the Psychopathic Hospital state: Physical examination negative. Oriented as to time and place. States he went to the Red Cross to look for some work and because he was nervous they sent him here. He often hears voices of women asking him when he is coming home. Some of his friends want to kill him because they are jealous of him for taking away their girls. When admitted to the Chicago State Hospital he was active, happy, and showed an elevated mood. Talked and joked about the things which happened to him before he came here. Was not resentful toward his aunt for committing him. Took everything as a joke. Denied hallucinosis. Told of some of the battles he was in while in France, stated he was a year and a half in France. He was at the front at Château-Thierry and at other places. Landed in the United States February 10 and was discharged February 14. He was feeling fine at that time. He went out and was celebrating for about three days and nights, drinking most of the time, but was intoxicated only once. Following this he became nervous and could not sleep. He remembered getting up and walking around at night. He felt fine even if he did not rest. He remembered telling his aunt he was doing guard duty but was only joking. Physical and laboratory tests were negative. This patient gradually improved, became less restless, took an interest in his surroundings, and was paroled July 25, 1919, as improved. He was returned on September 2, as he again had become restless, etc. He remained the second time until November 26, during which time he improved considerably, and then was again paroled and discharged February 25, 1920, as recovered.

Case XII.—Herman B., American Hebrew, 24 years old, single. Admitted to the Chicago State Hospital December 11, 1919. Family and personal history negative. Present trouble, as given by his mother: Patient was drafted June 1, 1917, but was not sent overseas. He was discharged February 22, 1918. He seemed normal and returned to work. Seven weeks before he was committed he became restless, did not sleep well, and had a very poor appetite. For three or four days he walked the floor day and night. A brother of the patient went to the bad and the police were searching for him, and the patient worried about his brother's actions. He then developed the idea that he himself would be mistaken for his brother and be locked up, as he looked like his brother. He thought that the police and detectives were following him. While he was in the Psychopathic Hospital he thought that his mother's head was cut off and that his sister had been killed. However, after he had been there two or three days he forgot about it. One day when his sister visited him at the Psychopathic Hospital he would not let her come into his room, saying he had an infectious disease and she might take it. While at home he took iodine, saying he wanted to die. One day he took scissors and a knife, saying he would kill himself. He turned on the gas but he turned it off again, saying he was afraid he might injure the children on the floor. Said he would jump into the lake. Cried all the time, saying he was innocent and why should everyone look on him in this strange manner. Said he was going crazy. The records from the Psychopathic Hospital Stated: Patient is oriented. Memory and retention good. Calculation and judgment good. Stream of talk. Patient entered hospital voluntarily for depression and insomnia and since his entrance has developed hallucinations and paranoid delusions. Feels electricity and smells bad odors; thinks his food is being poisoned, that people are after him, and that we have murdered his mother and sister. Emotional attitude depressed. When admitted to the Chicago State Hospital he was agitated and anxious, would pace the floor and wring his hands. Talked and moaned to himself. He developed ideas of references and unworthiness; said people watched him and talked about him; had auditory hallucinosis of a depressed nature. A week later he told the physician he was hearing voices in both ears. They asked him if he killed his mother and if he did, why? He was to figure out whether he was dead or not. He was very religious. He kept muttering to himself, many of his phrases coming impulsively without external stimuli. He spoke a great deal about his experience in the army, about God, about his business. Complained of stomach trouble and pain in the eyes, that his head was turning around and that he could not sleep. Talked back to the voices, saying he was not a dope fiend nor a murderer, he was not crazy, nor a bad man. He was apprehensive that he was going to die, to be shot or hung with a chain around his neck. He was oriented and clear with no psychomotor retardation. His general knowledge and memory were good, but showed some blocking. He would say: "I am twisted again. Electricity or something else; since in the other hospital, where they had electric baths and stuck me with pins and needles, I can't think straight." His physical and laboratory tests were entirely negative. A note dated February 25 states: Patient is depressed and cries a good deal. At times he asks to be killed. Has active hallucinosis and thinks his pepole are being murdered. A note dated March 1 states: Patient is receiving hydrotherapy. In conduct he is more quiet; in mood he is still depressed. He is more inaccessible now than before, but realizes he is not acting as restlessly as he did when admitted. A note on September 6, 1920, states: It is found that the patient, while still in the hospital, has improved considerably. He is not so agitated, but is quiet and well behaved. He is well oriented and has insight. He can give his name and the name of the hospital correctly; he knows how long he has been at the hospital, and gives the date correctly. When asked why he came here, he says that Dr. Meyer sent him to the Psychopathic Hospital, as he was nervous and could not sleep at night. Half of the time he would not eat or take care of himself. The reason he did not eat was because he had no appetite and he was discouraged. However, there was nothing wrong with his mind except that he was melancholic. At present, when he sleeps, he hears people talking to him, but he does not hear them while awake. He is better now than he was when he first came here, but does not think he will ever get his health back. He has no enemies. No one bothers him, nor is there any one after him now. States it was an imagination at the time he thought that people were after him. He realizes now that it was foolish for him to imagine such things. He is getting better in his head, but sometimes he gets pains in his stomach, possibly because he eats so much. The past six weeks he has felt better than at any time since he went to the Psychopathic Hospital. He wishes to go home now. He is clear. His personal identification is well given and his general knowledge is as good as can be expected from a man of his station, and he gives well the incidence of his commitment. When asked about the recent war, he states he was in the army ten months and he likes the army. He is sorry now that he did not stay in the army, as that is a great life; he learned there how to take care of himself, and he never was sick while in the army. His improvement was steady and he was paroled September 27, 1920, improved.

I could give the histories of many more of those cases. The Chicago State Hospital has admitted several hundreds of such cases, not all of them, however, running such a favorable course. The great majority are still here and run a course resembling that of the dementia precox group. However a close observer will easily distinguish them from the dementia precox group. The symptoms of postsomatic psychosis are: Sudden onset; fear; confusion, from a mild degree in which the patient is unable to tell time to a deep one in which he is even unable to find his way about the ward; slight amnesia; hallucinosis mostly of the auditory type. Physical findings of exhaustion; in some cases the physical findings may even simulate paresis in the

Argyl-Robertson pupil, speech defects, ataxia, etc. Right here I may state that the very fact that we find physical and mental symptoms resembling general paralysis in post-somatic and exhaustion neuroses and in veronal, bromide, and chloral poisoning goes to prove that the symptoms of general paralysis are not due to the location of the spirochetes in the brain nor to their destruction of neurons, but it is due to toxins which the spirochetes liberate. The prognosis of post-somatic psychosis is better than that of dementia precox and general paralysis. From 40 to 50 per cent. recover under proper treatment.

Etiology.—No more is known of the etiology of post-somatic psychosis than is that of any other psychosis. However, the mind is a biological force due to reactions of cells or a biological reaction, and cells will react to the kind of nourishment they receive and their environment. By modifying the culture media and temperature we can convert virulent bacteria into comparatively harmless ones and the reverse. By changing the food and environment we can change some vicious animals into harmless ones and some of our domestic animals into vicious ones. In all infectious diseases the circulating serum is changed owing to the formation of antibodies which are more or less of the nature of a globulin. However, they differ in their composition and reactions and we are inclined to call them now the albumins. We find them sometimes in the cerebrospinal fluid. Some will be precipitated by butyric acid but not by ammonium sulphate; while others will be precipitated by ammonium sulphate but not by butyric acid. Others again will be precipitated by phenol but not by either ammonium sulphate or butyric acid, others again will be precipitated by colloidal gold in various dilutions. So far the antibodies have been studied on the side of the good they do to the organism but not on that of the damage they do. In one disease, syphilis, where we can measure to some extent the antibodies by the Wassermann reaction, we actually find that the improvement in the patient goes hand in hand with the disappearance of the antibodies. The mental symptoms in patients recovering from an infectious disease may be due to the alteration in the serum which causes the neurons to react differently. What is true of infectious diseases is also true of pregnancy. In pregnancy antibodies are formed in the mother to counteract the destructive tendencies of the ovum toward the mother's tissues. The same is true in alcoholics. In alcoholics there is also something formed to neutralize the injurious effects of excessive indulgence in alcohol. In trauma, during repair the serum must surely be altered. In soldiers, especially during the war, the fact that the hardships and fear that influence so much digestion and the organs of internal secretion may also alter the serum in the blood should surprise no one. We may conceive that, in the majority of people after returning to normal, the altered albumins will be reconstructed by some of the organs of the body of which the liver, thyroid, and suprarenals seem to play the chief role. While in others those organs for some reason or other do not reconstruct the altered albumins in the serum and a psychosis will result. More research along these lines is very desirable.

Treatment.—Prophylaxis. Great care must be exercised by the physician in the case of patients who are recovering from bodily ailments or from confinement. Many patients are allowed to get up and take upon themselves the responsibilities of life too soon. We must assure ourselves that the patient has recovered sufficiently before he is allowed to take up his previous vocation, and then he or she should take up this previous vocation gradually. As post-somatic psychosis is apparently due to an exhaustion of the neurons or to an albuminous body circulating and irritating the neurons, our aim must be to strengthen the neurons and to destroy that albuminous body. The best nerve tonics we have are nuxvomica, continuous baths at a temperature between 90 and 94° F., massage, salt rubs, moderate exercise, easily digested and wholesome food, such as fresh eggs, chopped meat well stewed, plenty of milk, fruit, and fresh vegetables, and cheerful surroundings. So far as the destruction of the albuminous body is concerned, we know that the liver, thyroid, and suprarenals are the principal organs whose function it is to do that work. We must see to it that those organs functionate properly, or if they do not we must help them by supplying thyroid extracts and adrenalin as indicated. Unfortunately we have not as yet isolated anything that will take the place of the function of the liver cells. However, ox-gall is known to stimulate the liver cells to greater activity and it should be tried in cases where we suspect that these do not functionate properly. The symptomatic treatment by means of laxatives, sedatives, etc., when needed, must be left to the discrimination of the attending physician.

OBSERVATIONS ON B. ACIDOPHILUS:*

ITS BACTERIOLOGICAL CHARACTERISTICS AND POSSIBLE THERAPEUTIC SIGNIFICANCE.

BY LOUIS M. GOMPERTZ, M.D.,

NEW HAVEN, CONN.

ASSISTANT CLINICAL PROFESSOR OF GASTROINTESTINAL DISEASES, DEPARTMENT OF MEDICINE, YALE UNIVERSITY.

AND

MARTIN G. VORHAUS, M.D.,

NEW YORK

BACTERIOLOGIST, HARLEM HOSPITAL.

THE interest of the medical profession in intestinal microorganisms was first aroused in 1880 by the discovery and isolation of the *B. typhosus* by Klebs, Eberth, and Koch. Nothing was known at that time of those organisms which have since been called the typhoid-colon group, so that when Escherich announced the discovery of the *B. coli* a distinct and important step was taken towards a lucid classification of fecal bacteria. Yet it remained for Tissier to prove that Escherich had included the *B. bifidus* with the *B. coli*, and in his publication definitely differentiated these two groups of fecal bacilli. With this announcement, the Gram positive bacilli became the subject for investigations and finally in 1900, Moro described the *B. acidophilus*, giving its distinctive characteristics.

It is with this organism that our study has been carried on. Before setting forth some of the results of this work, let us briefly consider the bacterial

*Read before the American Gastro-Enterological Association, June 6, 1921, at Boston, Mass.

changes in the human intestine from birth to adult life.

The meconium is sterile, but immediately after birth becomes invaded by microorganisms. Their number, however, is never large, as meconium is a poor culture medium. Nevertheless, *B. coli* has been recovered from meconium passed ten hours after birth. The intestinal flora of the breast-fed infant is predominately Gram positive and consists chiefly of *B. bifidus* and *B. acidophilus; B. coli* and other bacteria are present, but in insignificant amounts. The flora of a bottle-fed infant, however, shows a goodly number of *B. coli, Streptococcus lacticus*, and staphylococci, although *B. bifidus* and *B. acidophilus* still predominate. As soon as milk ceases to be the main constituent of the child's diet, the Gram positive element of the intestinal flora rapidly diminishes and *B. bifidus* and *B. acidophilus* exist only in small amounts.

In the adult, the character of the intestinal microorganisms is dependent largely upon the nature of the individual's diet. With the normal mixed diet, the *B. coli* and allied bacteria are found in high predominance, completely overshadowing the *B. acidophilus* which is often found only after a prolonged search. The adult on a milk diet, however, has a considerable number of Gram positive *B. acidophilus* in his feces, and at times, on an exclusive milk diet, these organisms even predominate the intestinal flora.

However, the great majority of adults ingest large, if not excessive, amounts of protein and the average fecal flora is composed of from 80 to 95 per cent. of *B. coli* and allied bacteria. It is in these individuals that we so often find extensive intestinal putrefaction.

For years, the large intestine has been regarded as furnishing the etiological factor responsible for many diseased states, and it was the trend of medical thought that in whole or in part, the absorption of bacterially split protein derivatives was causing the premature onset of senile changes in the arteries, heart, kidney, and so forth. So that when Metchnikoff in 1906 offered his Bulgarian bacillus as a means of destroying the *B. coli* and thus eliminating or minimizing intestinal protein putrefaction, it was hailed with considerable enthusiasm. We know now, however, that the administration of large doses of live *B. bulgaricus* cultures does not decrease the number of *B. coli* present in the intestines of animals or man; and furthermore it has been conclusively demonstrated that *B. bulgaricus* cannot be implanted in the human intestine in spite of radical changes in the diet. But Metchnikoff's work has not been in vain and his ingenious theory has inspired others to find a means of holding in check the *B. coli* in vivo.

For some time Rettger of Yale and his coworkers have experimented with *B. acidophilus* on animals and man. They have shown definitely that this organism can be implanted in the intestinal tract and that coincident with this implantation there is a gradual decrease in the number of *B. coli* to a point where they represent 10 per cent. or less of all the fecal bacteria. Their experiments with rats have also shown that this same effect may be produced by the ingestion of large amounts of lactose or dextrin.

Rettger's important bacteriological findings suggested to us a clinical study of this organism and we began administering *B. acidophilus* cultures to a number of human subjects suffering from marked chronic constipation with its typical and well-known symptoms. Encouraged by the markedly beneficial results reported to us by these patients, we then turned our attention to that large variety of intestinal disorders known as the chronic diarrheas, the results of which will be mentioned later. We will now discuss the method of administering the *B. acidophilus* cultures.

At first fermented milk was given. This was prepared by inoculating sterile milk with *B. acidophilus* and allowing it to incubate at 37.5° C. for from forty to fifty hours. Either whole or skim milk may be used. The dose is from a pint to a quart daily given preferably before meals in amounts ranging from one-half to one tumblerful. This method, however, proved to be inconvenient from a practical standpoint, thereby necessitating a different means of administration. A broth culture in which this bacillus grows luxuriantly, giving the optimum concentration, was finally used.

The broth is so prepared that each c.c. contains one hundred million *B. acidophilus* organisms and the dose is from 10 to twenty c.c., two, three, or four times a day, before meals, depending entirely upon the response of the individual.

The technique of preparation of the broth is simple and is as follows:

1. To 1000 c.c of distilled water add
   4 gms. Liebig's meat extract
   10 gms. Merck's peptone and
   5 gms. sodium chloride.
2. Heat over free flame until thoroughly dissolved, stirring constantly.
3. Titrate and adjust to required reaction; *Ph.* 6.9—7.0 *neutral.*
4. Sterilize in 1 liter flasks for 1 hour in Arnold sterilizer.
5. Filter bouillon *cold* the next day through filter paper, until clear.
6. Add to clear bouillon, to 1000 c.c. 50 gms. of lactose (5 per cent); shake well, until sugar is dissolved.
7. Pour media in flasks (300 c.c. in each ½ liter flask).
8. Place the flasks, stoppered with cotton, in the autoclave for 25 *minutes* and sterilize at 15 *pounds pressure.*

These flasks are then inoculated and incubated at 37.5° C. for about sixty hours. They are then removed and the clear supernatant fluid is decanted. This simple procedure gives approximately a concentration of one hundred million bacilli to each c.c. The culture is then distributed in sterile eight-ounce bottles and kept cool until used.

In this medium *B. acidophilus* grows luxuriantly, although growth is not perceptible until the end of forty-eight hours. This fact is of considerable practical importance for it affords a simple and yet accurate means of determining the purity of the growth. The usual laboratory contaminants, which are the *Bacillus subtilis* and *Staphylococcus albus*, show a luxuriant growth in this medium at the end of twenty-four hours. Furthermore, these contaminants are more or less evenly distributed and the

contaminated flasks show a uniform density. The growth of *B. acidophilus*, however, is a thick, heavy, slimy growth which settles quickly to the bottom and leaves a clear supernatant layer of bouillon above. Thus the contaminated flasks are easily detected and thrown aside.

The *Bacillus acidophilus* is Gram-positive, varying in shape from short to long rods. On lactose agar it forms small whitish-gray colonies with wavy margins. It grows slowly, being hardly perceptible at the end of twenty-four hours. This organism ferments milk, producing acid slowly so that the milk does not usually begin to sour until incubated for about thirty to thirty-five hours.

Recently, in the preparation of this broth, sodium phosphate instead of sodium chloride has been used. This salt acts as a buffer, and by neutralizing the acid formed, will, we believe, increase the length of time of viability of the culture. This work, however, is still incomplete.

In carrying on this clinical study, *B. acidophilus* cultures were first administered to individuals whose only obvious ailment was chronic constipation. These patients have been under constant observation for a period covering five months or less. Only cases of the severest type were chosen, and particularly those of many years' standing. In a short time these subjects experienced considerable relief and maintained, while on the treatment, a state of excellent health. The following is an illustrative case:

The patient, a male, fifty-two years of age, a professor in Yale University, had been constipated since boyhood. For twenty years he had never had an action of the bowels except by means of cathartics, which were taken daily. He has been troubled with repeated attacks of erythema multiforme and at one time had a persistent eruption which was finally found to be due to phenophthalein. Has worked hard, but latterly felt his ambition waning without being actually ill. His urine was loaded with indican and the stools were dark, very foul, and filled with colon bacilli. January 18, 1921, he was put on *B. acidophilus* culture in two-teaspoonful doses, four times daily and all cathartics were stopped. For three days he had no action of the bowels; then there was a copious stool, and since then there has been a normal daily movement. The stools are yellow, formed, and inoffensive. Indican has disappeared from the urine. This man states that he feels better than he has for a long time.

Of fifty cases of chronic constipation, forty-two gave satisfactory results. Of the chronic diarrheas, again only the severest cases were tested, and to date ten cases out of twelve have shown marked improvement. These individuals have been under constant observation ranging from three to five months.

The following is an illustrative case of mucous colitis of six years duration:

A woman forty-three years of age has had painful intestinal contractions with the evacuation of large quantities of mucus, which at times has been blood streaked and diarrheal in character. This patient was distinctly neurotic and had gone the rounds of osteopathic, chiropractic, and allopathic practitioners. She was given the numerous treatments recommended without much relief, and finally was placed upon *B. acidophilus* treatment early in February of this year. At first there was an increase of her bowel movements but the treatment was persisted in and after the first week, regular formed bowel movements began and have continued up to this time, accompanied by relief of her pain. The blood has entirely disappeared from her stool. During the treatment no restrictions whatever were placed on the diet in either type of cases.

Bacteriological and microscopical studies of the feces have been made on patients and show the same changes as Rettger demonstrated. Before treatment, the fecal flora showed Gram negative bacilli (the *B. coli* group) in high predominance, often representing ninety to ninety-five per cent. of all fecal organisms. From two to three days after the beginning of the administration of B. acidophilus cultures by mouth, they are first demonstrated in the stool. From that time on they increase in number until on the fifth or sixth day they represent about ninety per cent. of the fecal microorganisms. At the same time there occurs a proportionate decrease in the number of *B. coli* until they are present as less than ten per cent. of all the intestinal bacteria. From the sixth day on, while the culture is being taken, the fecal flora consists predominantly of Gram positive rods, regardless of the character of the individual's diet.

When the administration of the culture ceases, the *B. coli* begin to increase, slowly at first, until the fifth or sixth day, at which time they again are present as the predominant type of bacteria. If, however, lactose or dextrin is included in the diet, this transition may be retarded considerably.

As the change from Gram negative to Gram positive flora takes place, there occurs a change in the physical characteristics of the feces. The fecal masses become larger, softer, lighter in color, and comparatively odorless, while evacuation is unattended by griping pains. The stool, moreover, is usually formed, regardless of the amount of the culture ingested.

The work of Rettger mentioned above, has opened up a large field for investigation. In this paper we are reporting the results of a small clinical study. The results are highly satisfactory and we hope to continue work along similar lines. The therapeutic properties of *B. acidophilus* are still in the experimental stage, but it is safe to say that the value of this form of treatment promises much hope for the future. Serious consideration should also be given as to the best methods to be employed for its administration.

However, as a result of this study we feel justified in drawing the following conclusions:

1. *B. acidophilus* when given by the mouth can and does implant itself in the intestinal tract.

2. The administration of *B. acidophilus* is accompanied by a marked decrease in the number of *B. coli* in the feces and the supplanting of these by the *B. acidophilus*.

3. In chronic constipation there was marked improvement from the so-called toxic symptoms and relief from the constipation which coexisted.

4. In the chronic diarrheas there was an abatement of the symptoms.

WHAT THE STATE DEMANDS OF ITS SENTINELS OF MENTAL HEALTH.

BY DONALD A. LAIRD,

IOWA CITY.

RECENTLY LECTURER FOR THE INTERNATIONAL CHAUTAUQUAS; RESEARCH ASSISTANT, UNIVERSITY OF IOWA; FORMERLY EXAMINER, PSYCHIATRIC UNIT, GREAT LAKES NAVAL TRAINING STATION.

WE may take as our point of departure the self-evident proposition that results most beneficial to the mental health of the community are to be accomplished, not in the wards of the State hospitals, but in the community itself. It would be erroneous to infer from the above platitude that one can be blinded to the vast sway of influence over the mental welfare of a community which is exerted by these hospitals the States have provided for the rehabilitation and care of its maladjusts of behavior. Certainly I would be the last to berate the potency of the State hospital as a factor in the mental health of the community. But as a point of departure for the short survey we have before us we will consider a very significant factor external and to some degree foreign to these bulwarks of mental hygiene.

Perhaps what we are to consider is the most significant factor in mental hygiene. Of course no one can definitely decide such a point, but at times—very frequent and recurrent—I am inclined to throw discretion to the winds and emphasize it as *the most*.

Before divulging the identity of my *the most* it may profit us to box the compass, as it were. Certainly an orientation and general view over the whole glorious and growing field of general public (and individual for that matter) hygiene or health is not amiss on any occasion. And mental hygiene, either community or individual, is essentially a part of general hygiene and as such needs to be approached as a part of the field of preventive medicine. True, it may be that mental health problems are more complex, apparently more obscure, and in many instances more difficult of approach than problems in general physical well-being, but this very fact should be a challenge to the mental hygienist to sit himself down occasionally and take stock of things in the general province of health welfare. It is advisable for the mental hygienist to do this that he may keep in touch with reality and not deteriorate into a species of ex-cathedra oracle, maintaining a secluded existence and attempting to accomplish his great work alone, unaided, and outside the usual channels of hygienic activities.

Mental welfare itself will progress most and be of most serviceable value when it is substantially incorporated into the aggregate comprising general hygiene. And hygiene itself will not be measuring up to the demands and possibilities of its work until the general hygienist is also qualified to a certain extent as a mental hygienist. Until this desideratum is achieved and *mens sana in corpore sano* receives, not less emphasis upon corpore, but *more* emphasis upon mens, hygiene will still remain a microcephalic monster, unable to meet in an adequate manner a large portion of the problems in hygiene which loom dark and ominous on the horizon.

Now back to our opening platitude. In modern health work we find the predominant tendency is to carry the most intensive work from the hospital, clinic, dispensary, or what not, directly to the doorstep and into the lives and daily routine of the people of the community. The hospital with its specialized services and facilities is an indispensable feature of all the hygienic agencies at present. However, in that hygienic Utopia which it is always well to keep in mind, one will find no hospitals as we now think of them and know them. If there were hospitals as we now know them they would have nothing to do, the community being so effectively barricaded against ill-health through the labors of the hygienists, that even such surgical emergencies as accidents would not put a single patient into our already deserted hospitals. In this ideal, and at present extremely nebulous community, hospitals would become extinct by the action of natural selection. They would be eliminated by a more fit and vigorous institution known as hygiene.

The picture has been overdrawn? Well, perhaps it has but ever so slightly, and one cannot fail to appreciate its full representative value as indicating the potentialities and trend of hygiene. This hygienic Utopia represents, also, an inspirational working hypothesis for all those engaged in any phase of the stimulating and ever pressing and increasing work of public health. The sum and substance of all adequate theories and facts which are pertinent in this connection is that preventive and prophylactic sciences can largely accomplish the end results which have been pictured in our Utopia. Solemn social, scientific, moral, and medical obligations unswervingly demand that in hygiene the practical results should no longer fall so far behind the potential possibilities which lie close at hand.

In mental hygiene one finds this Utopia more distant than perhaps in all the other branches of hygienic endeavor. In the realm of mental hygiene, especially, it is not quixotic to hope and maintain that this Utopia of psychic salubrity is possible of achievement. Mental hygiene should, like all the other preventative sciences and arts, focus its attention upon causes rather than irrevocable effects. The mental hygienist should concentrate his prophylactic efforts upon the everyday activities of the personality in the household, in the street, in the factory, or in the forum.

Social expediency—which in this case, as usually, means social ignorance and bias—may deem it more essential to retain the emphasis upon the hospitalization of the maladjusted personality. As a hygienic science and art, however, it is the first duty of mental hygiene, in point of time, to clean up the *beau idéal* of social and political expediency. This has in part been largely accomplished. The first duty, in point of emphasis and permanent hygienic value, is for mental hygiene to reach the personality long before it becomes persistently headed toward the institutions of social convenience. To accomplish this—and it is capable of accomplishment—would demand an adequate mental hygiene from birth if not before the formation of the first blastomere that is later to become that indefinite, yet meaningful thing we choose to call the personality and with which mental hygiene is chiefly and vitally concerned.

One occasionally finds some sort of a distinction attempted between normal mental hygiene and abnormal mental hygiene. At this point we may fittingly question if so-called abnormal mental hygiene is hygiene in the intrinsic meaning of the term or if it is a spurious sort of hygiene, necessary enough and valuable enough in itself as a deserving field of endeavor, but aside from the direct delimitation of the term hygiene and that which is for greatest permanent progress in mental welfare. Strictly, yet broadly, defined at present hygiene, is "that department of knowledge or practice which relates to the maintenance of health" (New Oxford Dictionary), or "the science that treats of the laws of health and the methods of their observance" (Gould's Practitioners' Medical Dictionary). And plainly enough, beyond all controversy, the maintenance of health and the observation of the laws of health are far more than merely the absence of disease. Evaluated in terms of the accepted present-day designations of hygiene in fields other than mental we find that so-called abnormal mental hygiene is an impostor. We do find, however, in the 1811 edition of Hooper's Medical Dictionary "some modern [1811] physicians have applied this term [hygiene] to that division of *therapia* which treats of the diet of the sick." This abnormal mental hygiene is essentially little more than a "division of therapia" and as such reverts to the hygiene of over a century ago. At the present day it is indeed *abnormal* hygiene!

There is a place for abnormal mental health work in the field of public health, but this is a *sanitary* science and not hygiene. Those psychiatrists who concentrate their efforts and attention upon institutional cases and overt maladjusts may be furthering knowledge and rehabilitating their patients, but they are not, *ipso facto*, hygienists. Not until psychology, psychopathology, medical psychology, and medicine use their hygienic tourniquets to dam the flow of personality into the State hospitals and sanitaria will the term mental hygiene be more than flim-flam and mockery.

The foregoing should not in any wise be construed to discredit the significant and epoch-making work in mental hygiene already accomplished by any of the existing central agencies organized for that purpose. Theirs has been a difficult and unwavering struggle in blazing the trail and naught but plaudits and encouragement should be bestowed upon them in recognition of the meritorious advances which they have fostered and won. The time is now at hand, however, when probably the largest portion of the active work in mental health activities as well as the most palmary work in this field resolves itself upon those who are the local and intimate custodians of the mental health and welfare of the community.

It is these local mental hygienists who have their fingers continuously on the pulse of the community and the personalities of that community ever under observation who will render greatest aid in lessening the flow of these personalities toward the colossal monuments to mental as well as physical and social maladjustment—the State hospitals. As in the case of typhoid fever, for example, where sources of infection must be guarded against and carriers identified and freed from their potential danger to the body politic and where it is essential that the patient be given early treatment and not simply care, so in mental adjustments the possibilities for undesirable and pernicious adaptations must be guarded against individually and collectively and the early prodromal signs of maladjustments observed that readaptations and regulations may be effected. Those to whom this duty falls are the outposts, the sentinels of mental health. Theirs is the most imperative and constructive work in the conservation of mental health, happiness, and social and economic values.

And now one might ask who are these sentinels on guard over the mental welfare of the community? Is it the priest? Is it the teacher? The parents? Is it the social service worker? Is it the medical man? Is it the lawyer? It is all these and many more, for mental hygiene involves the entire individual, since all of his components are concerned in a rather intimate way with the personality and all the above are to a considerable extent in a position of vantage for sentry duty in mental hygiene. There is one, however, who should be signaled out above all others as the sentinel supreme—the family physician or the general practitioner.

It is the general practitioner who is in a position to accomplish the greatest results in constructive mental hygiene for the community as well as for his clients. Moreover, it is in his line of duty to do this. From the approach of real, not spurious, mental hygiene the family physician is undoubtedly in a far more strategic position

than the highly trained and specialized neuropsychiatrist. The general practitioner who is alive to his opportunities can largely bring about the realization of our hygienic Utopia in the mental sphere on a much larger scale and in a more natural and advantageous manner than the mental specialist who comes into contact chiefly with those cases in which the family physician either has neglected or failed to measure up to his hygienic functions.

There is another who, next to the family physician, should be mentioned in passing as also being in a position of supreme vantage for this type of sentry duty. I have in mind the clergy; not the newer variety of "religious executive" who is working principally in group terms and concepts, but the older and persisting priesthood that is interested, perhaps solely, in the parishioners of the church. It is this type of hierophant who not only leads and instructs his laity in the faith but also holds a crucial, priestly relation with each of his individual parishioners who is in a position to stand guard over the mental health of a rather large and already segregated communty in a manner unexcelled even by the family physician. Except in rare and encouraging instances one does not find the background of training and the points of view among the clergy that will enable them to approximate in any appreciable extent the positive results in mental welfare which should be a part of their ministrations.

This crucial position of the clergy is reflected somewhat and indirectly in the development of the institutional care of overt cases of maladaptation due largely to addled mental functioning. The early custodial institutions of social convenience were largely under the supervision of ecclesiastical workers whose motives were in the main humanitarian. By the early nineteenth century it had come to be generally realized that the *non mentis compos* was more than an object needing gentle and firm ministrations. It was about this time that medical and scientifically minded men seriously began to turn their attention intensively toward these mental, biological, and social maladjusts. Hard-headed law makers and law diviners soon came to see that here was a need for care directed by the head as well as by the heart. Obviously such custodial work demanded as a preparation medical, psychological, and scientific training rather than simply theology and high motives, although these are by no means to be neglected or despised.

At the present day we find every progressive State using medical opinion largely and almost solely in the selection of those who need the care provided by the State hospitals. In practically every State the legal machinations demand that cases for commitment be passed upon by physicians duly qualified under the State Laws. This is the rôle of the general practitioner in mental health supervision, as has been defined by the States.

Beyond the peradventure of a doubt this is not constructive, well-rounded, or economic mental hygiene if it is hygiene at all. It is little more than social expediency with an admixture of a grain of individual rights. The State is apparently unconcerned with the personality of its citizens before deterioration is so far advanced or so badly disordered in its functioning that the commitment stage is reached. It becomes the responsibility of the family physician, however, as a scientist to some extent and as a guide in the observation of the laws of health to keep a vigilant watch over the mental welfare of his clients fully as much as their organic welfare is closely guarded. I rather doubt if there is a family physician who would feel that he justified his medical training and his fees if his duties were limited to stand passively by his patients until the time came when he could say: "After thorough, detailed, scientific and unbiased examination I pronounce this individual dead." But is not this about what the State expects of its physicians as mental hygienists (save the term!)? After thorough, detailed, scientific, and unbiased examination the family physician pronounces the personality fit for commitment!

As we now proceed with our subject we are going to investigate the consistency of the State in even this narrow responsibility in mental health work which it legally thrusts upon those who by the nature of their work and their obligations to their clients should be the mental hygienists par excellence. More specifically we will inquire into the qualifications which the State demands of its sentinels of mental health as it now conceives of them in order that it may be assured of their competency in duty.

Legal walls in the form of the State medical licensing and examining boards have been erected by the various States to protect their citizenry against charlatans and medical frauds. It is the chief function of these boards to inquire into the fitness of those who would practise medicine within the respective States and issue certificates or licenses to those who measure up to certain prescribed standards. These standards are, in a large measure, legally established and detailed in "legislation by reference" in the statute books. Such standards as set forth in the State statutes usually prescribe graduation from a "recognized" medical college, a certain moral fitness, a few educational requirements, and an examination of the candidates by the State board.

As a rule, a great latitude is given the State board; most of the medical practice acts, for example, permit the boards to decide what schools shall be accepted as "recognized" medical schools. Especially in the matter of the examinations have the law makers judiciously given the medical boards free reign. One might therefore be led to expect great individuality in these boards, but such is not the case. Of course there are varying degrees of exactness in the requirements but, by and large, approximate uniformity is the rule among these boards.

It is these boards that pass upon the fitness of those whom we have found to be the sentinels, par excellence, of mental hygiene. The States themselves have also found that those licensed by these boards are mental hygienists, but, as we have already indicated, the official duties as such hygienists are very narrow and unproductive. The fact remains, however, that in almost every in-

stance it is the licensed practitioner who is called upon by the State in cases of maladjustment involving commitment to State care.

In view of the significance and urgency of all hygienic work, and especially work in mental hygiene, one is led to wonder just how rigorous are the requirements established by the States and interpreted by the licensing boards to insure proficiency on the part of the practitioner in this respect. As near-sighted citizens and taxpayers we want to be satisfied that the men officially recognized in the commitment process do not fill our State institutions with unnecessary charges. As far-sighted citizens and taxpayers we want to see what qualifications are demanded of those who should early recognize inimical mental conditions and ameliorate those in so far as is possible before commitment becomes imperative.

The most that the State boards can expect from their candidates at present, aside from a special interneship or other special training after graduation, is a diploma from a class A medical college. And what specific preparation for work in mental hygiene, either in a broad or a narrow sense, can be universally relied upon from graduates of these class A medical schools?

In defining the standards to be met by acceptable medical colleges the Council on Education of the American Medical Association wisely permits of a short range of eclecticism in the clinical years of instruction. Certain clinical requirements are definitely stipulated, however. Such is the case in obstetrical experience. But nothing is set up as a goal for nervous and mental diseases or psychiatry or mental health training. It is stipulated that hospital facilities shall be available for children's diseases, contagious diseases, and nervous and mental diseases. No definite experience is particularized, however, and definite instruction in psychiatry is not mentioned. None of the premedical educational requirements specified for these acceptable schools includes psychology as a *sine qua non* for preparation, so one cannot expect the final product of the class A school to be invariably or usually equipped with the background essential for a comprehension of the "normal" mental hygiene which we have found is the real hygiene.

Only a limited number of the acceptable schools have a separate department of psychiatry or a distinct professor of psychiatry. What instruction is given in this field is usually by "bicycling" or by calling upon a state hospital physician for a few lectures. Instruction is usually of the manikin type and the clinical experience is incidental and vicarious. Many schools are frankly reluctant to include psychiatry in their curriculum which is "already crowded with more necessary subjects."

What preparation in this direction can the State boards expect from the graduates of the upper level of medical schools? A dozen or two lectures giving clinical epitomes, and observation of a few scattering, curious, and incidental "mental cases" is about all the training the medical graduate has received. Many admittedly receive no training at all.

We have now briefly reviewed what the State boards may expect by way of training in this branch of medicine from the average run of candidates for licensure. We will now turn our inquisitive attention to another aspect of the State requirements for licensure—the State board examinations. It is in these examinations that the State board is sovereign in determining, as the ultimate criterion, the candidate's fitness.

And just what do the State boards exact from their examinees as a demonstration of capability in mental hygiene? We will find an answer to this in the complete questions which are at hand for one State board examination in each of twelve States in 1920. A total of 1,051 questions are in these examinations. There are seven questions out of this number which can definitely be considered as directly testing the candidate's fitness as a sentinel of mental health. These seven crucial questions were distributed among four States only. The remaining eight States made no effort during the year in question to probe their candidates' fitness in this respect.

Of the four States that did consider their practitioners' capability as mental hygienists of sufficient importance to examine into this phase of their information, we find one State asking four questions (out of 120) on this topic. This State was Texas. Three of these questions were included under jurisprudence and one under pathology. Two other States included one pertinent question under the quiz on practice of medicine, while another State had one under obstetrics.

Thus we find that the States demand meager, if any, definite training and knowledge of psychiatry or mental hygiene as qualifications of its sentinels of mental health. Consistency, thou art a jewel—and rare! The States have designated as "experts" and certified as such those who have not been formally tested and in most cases not even schooled in their field of "expertness." It cannot be securely contended that a general medical education devoid of all direct contact with mental hygiene problems still prepares the practitioner for this sanitary service which is inseparable from his daily calls. But this is apparently the attitude taken by the State in licensing its physicians and designating its commitment experts.

Obviously the general practitioner is rarely qualified for even giving the advice in commitment cases requested from him by the State. And as sentinels of mental health one can rationally expect but little from this group. Somewhat limited but very pertinent data are available on these points.* This condition is also generally recognized, as witness the recent appearance of a paper giving a textbook summary of the prominent symptoms of mental disease as a leading article in a nationally recognized and circulated medical journal.

Statistics which are freely available and perhaps overworked, prove conclusively that there is a genuine and pressing need for sentinels over the mental health of the communities. It is more than a theory or a hobby or a passing fad. It is

*"Does there exist a need for a program of education in mental hygiene?" *Mental Hygiene*, iv, 2, pp. 393-403, April, 1920.

recognized by hard-headed men of business and cautious scientists as being a very practical problem and not simply sentimental twaddle. That even moderately trained sentinels can really bring almost miraculous results to pass has been demonstrated beyond question. What, then, is to be done?

Well, something is being done. For instance, the Board of Registration in Medicine of the Commonwealth of Massachusetts is considering demanding a medical course in psychiatry or nervous and mental diseases from its candidates. It is also probable that at a future date this progressive board will notify the medical schools that all applicants will be examined in neurology, including psychiatry. It may be that other States are considering similar action. Surely it is the only economic policy for the citizenry to be assured of the fitness of their family physicians as mental hygienists in phases of personal efficiency as well as commitment.

There are a few States which have the facilities available for training in mental hygiene as a State project. The licentiates could be given training at these centers before being permitted to practise and with bounteous remuneration to the State as well as to the embryo practitioners. To take New York State as an example. This State has a splendid psychiatric institute on Ward's Island which is used largely for training of the physicians in the service of the State hospitals. If it has been found necessary to provide special post-graduate training for those in charge of the overt and total maladjusts, there is certainly greater need for training those whose duty it is to nip in the bud, so to speak, the potential and the beginning maladjusts. And in the case of New York State one finds an established institution which is admirably fitted for giving that training.

One might say in paraphrase that the State wants but little nor expects that little well done from its sentinels of mental health. This policy of *laissez faire* is costing the citizenry millions of dollars annually and is casting up an ever-increasing number of wrecked personalities on the sands of our high tide of civilization. It is decidedly uneconomic as well as unhygienic to permit conditions to remain as they now are; and it is entirely within the powers of the States to change conditions for the better. Until the States and their practitioners awake to the realization of their duties as sentinels of mental health we will continue to witness the passing of 60,000 personalities annually into the State hospitals for mental diseases. And are the States going to allow these floodgates of waste to remain wide open?

Is the family physician going to remain content to stand by in ignorance while one out of each hundred of his clients becomes so badly adjusted that an efficient, normal life is no longer possible? And, since health is more than the absence of disease, what is the family physician going to offer his clientèle in the way of promoting sound mental health, efficiency, and happiness? As a sentinel of mental health, the family physician is the keystone in the arch of hygienic progress, and not until the States demand adequate qualifications for this sentry duty will the ebb and flow of human personality between disease and inefficiency be lessened.

SIXTY-FIVE CASES OF CERVICAL RIBS.

By I. S. TROSTLER, M.D., F.A.C.P.,

CHICAGO, ILL.

CONSULTING ROENTGENOLOGIST TO ST. JOSEPH'S, AMERICAN, ST. FRANCIS, NORWEGIAN-AMERICAN AND WEST END HOSPITALS.

In making this report of an intensive study of 65 cases of cervical ribs, I do not expect to present anything new and startling regarding diagnosis; but I will endeavor by the tabulation of the radiographic findings with the symptoms, clinical findings and a very brief history in each case, to present such items as will make it of interest to all who meet these cases, and possibly of some value as a general aid in the diagnosis.

Cervical ribs are much more common than is generally supposed, and the diagnosis is so very easy when one has the condition in mind, that the writer has frequently surprised the referring physicians by the ease and certainty that a diagnosis was made before the *x*-ray examination, which verified the diagnosis.

The diagnosis was correctly made by the referring physician in only 17 cases (26 per cent.) of the 65 cases under discussion. Neuritis from unknown cause was diagnosed in 28 cases, progressive muscular atrophy in 9 cases and no diagnosis attempted in one case. Nine of the examinations were made for other purposes and the finding of cervical ribs was only incidental.

The number of cases in males was 21 (32 per cent.) and in females 44 (68 per cent.).

The number who had cervical ribs on the right side only, was 3, on the left side only, was 4, and on both sides 58.

The number presenting symptoms and clinical findings on the right side only, was 28, on the left side only, was 20, and on both sides, was 9. Seven presented no symptoms.

The number with double cervical ribs who presented symptoms on the right side only, was 25; on the left side only, was 19, and on both sides 9. Seven cases presented no symptoms.

The age of the 65 patients was as follows:

20 years or less.....	5 cases	41 to 50 years.....	14 cases
21 to 30 years.....	9 cases	51 to 60 years.....	6 cases
31 to 40 years.....	26 cases	Over 60 years.....	5 cases

The youngest patient was 4½ years, oldest 65 years. Average age of the 65 cases was 39 years.

The duration of the symptoms in 58 cases was as follows:

Less than 1 year....	18 cases	5 to 6 years.....	2 cases
1 to 2 years.....	13 cases	6 to 8 years.....	4 cases
2 to 3 years.....	6 cases	8 to 10 years.....	2 cases
3 to 4 years.....	3 cases	10 to 15 years.....	3 cases
4 to 5 years.....	5 cases	Over 15 years.....	2 cases

Average duration of symptoms in 58 cases, 45 months.

Number of cases operated for cervical ribs from this series was 13. Of these 13 were improved or cured by the operation (100 per cent.).

The data in these cervical rib cases are presented in the accompanying table.

25 E. WASHINGTON STREET.

TABULATION OF SIXTY-FIVE CASES OF CERVICAL RIBS.

Case No.	Sex	Age	Duration of Symptoms	Clinical Diagnosis by Attending Physician	Roentgen Findings	Pain					Atrophy				Weakness				Paresthesia	Anesthesia	Circulatory Disturbance	Operated	Remarks
						Neck	Shoulder	Arm	Forearm	Hand	Shoulder	Arm	Forearm	Hand	Shoulder	Arm	Forearm	Hand					
1	M	40	7 years	Progr. Muscular Atrophy	Double Cervical Ribs		R	R	R	R	R	R	R	R	R	R	R	R			Venous	Yes	Improved in 6 months. Cured in 1 year.
2	M	45	3 years	Progr. Muscular Atrophy	Double Cervical Ribs	R	R						R	R		R	R	R	R				
3	M	32	6 Weeks	Tumor	Double Cervical Rib	L	L	L	L	L	L	L	L	L	L	L	L	L	L		Venous	Yes	Sarcoma of Left Cervical Rib.
4	M	44	5 Years	Progr. Musc. Atrophy	Right Cervical Rib	R		R	R	R		R	R	R		R	R	R				Yes	Much improved in 6 months. Cured in 10 months.
5	M	50	8 Months	Cervical Rib	Double Cervical Ribs	L	L	L								L	L	L	L				
6	M	35	3 Years	Progr. Musc. Atrophy	Double Cervical Ribs						R	R	R	R					R				
7	F	63	2 Years	Progr. Muscular Atrophy	Double Cervical Ribs	2	2	2	2	2	2	2	2	2	2	2	2	2					Symptoms on both sides.
8	F	27	6 Years	Cervical Rib	Double Cervical Ribs	R	R						R	R				R	R		Yes		Much improved in 6 months. Cured in 1 year.
9	F	42	10 Years	Progr. Muscular Atrophy	Double Cervical Ribs		R	R	R	R	R	R	R	R	R	R	R	R			Yes		Much improved in 8 months. Cured in $1\frac{1}{2}$ years.
10	F	50	1 Year	Neuritis	Double Cervical Ribs	2	2	2	2	2	2	2	2	2		2	2	2	2		Yes 2		Improved under As. but had relapse. Symptoms bilateral.
11	M	39	3 Years	R. Shoulder Neuritis	Double Cervical Rib	R	R	R	R				R	R	R	R	R	R			Yes		Left rib longest.
12	F	33	8 Months	Progr. Muscular Atrophy	Left Cervical Rib	L	L	L	L	L	L	L	L	L	L	L	L	L				Yes	Deltoid atrophy marked. Improvement prompt.
13	F	30	1 Year	Progr. Muscular Atrophy	Double Cervical Ribs	L	L	L	L	L	L	L	L	L	L	L	L	L	L		Yes		
14	F	45	5 Years	R. Cervical Rib	Double Cervical Ribs	R	R	R	R	R	R	R	R	R	R	R	R	R			Yes	Yes	Relieved in 2 months. Cured in 8 months.
15	F	54	11 Months	Neuritis, Rheumatism, etc.	Double Cervical Ribs			R	R	R				R				R					
16	F	36	2 Years	Pain	Double Cervical Ribs	R						R				R							Palpable rib in neck on R side.
17	F	53	$1\frac{1}{2}$ Years	Progr. Muscular Atrophy	Double Cervical Ribs	L					L	L	L	L	L	L	L	L					
18	M	29	2 Years	Neuritis	Double Cervical Ribs	R	R	R	R	R	R	R	R	R	R	R	R	R					
19	F	47	12 Years	Neuritis	Double Cervical Ribs	R	R	R	R	R	R	R	R	R	R	R	R	R					B. P. 200+. Marked arterio sclerosis.
20	M	33	4 Years	R. Cervical Rib	Double Cervical Ribs	R	R	R	R	R	R	R	R	R			R	R	R				
21	F	$6\frac{1}{2}$			Double Cervical Ribs																		No symptoms or physical signs.
22	F	27	3 Months	Neuritis	Double Cervical Ribs	R	R				R	R						R					
23	F	28	2 Months	Neuritis	Double Cervical Ribs	R	R				R	R						R					
24	F	48	1 Year	Neuritis	Double Cervical Ribs	R	R	R	R		R	R			R	R							
25	F	22	5 Years	Neuritis	Double Cervical Ribs		R	R				R											Small short ribs.
26	F	56	1 Month	Neuritis	Double Cervical Ribs					L				L		L	L	L	L				
27	F	36	10 Years	Syringomyelia	Double Cervical Ribs	2	2	2	2	2	2	2	2	2	2	2	2	2	L		Yes		Symptoms on both sides. Syringomyelia also present
28	F	30	$2\frac{1}{2}$ Years	Neuritis	Double Cervical Ribs	R	R	R			R	R				R							
29	F	39	3 Years	Neuritis	Double Cervical Ribs	R	R																Small short ribs
30	F	37	15 Years	Neuritis	Double Cervical Ribs	R	R												R				Small short ribs.
31	F	35	9 Months	Neuritis	Double Cervical Ribs	L	L												L				Small short ribs.
32	M	65	4 Months	Carcinoma of Larynx	Double Cervical Ribs																		Patient died a few days later of Carcinoma.
33	M	52	1 Year	Cervical Neuritis	Double Cervical Ribs	R	R	R	R	R	R	R	R	R	R	R	R	R	R		Yes	Yes	Relief in six months. Cured in 1 year.
34	F	35		Injury	Double Cervical Ribs																		No symptoms.
35	F	46	3 Weeks	L. Cervical Rib	Double Cervical Ribs			L	L	L		L	L	L		L	L	L	L		Yes		
36	F	50	10 Years	L. Cervical Rib	Double Cervical Ribs	L		L	L	L		L	L	L		L	L	L				Yes	Complete cure in 10 months.
37	M	35	1 Year	L. Cervical Rib	Double Cervical Ribs	L	L	L	L	L	L	L	L	L	L	L	L	L				Yes	Relieved in 3 months. R. rib longest.
38	F	50	4 Years	Neuritis	Double Cervical Ribs	R			R	R			R	R			R	R	R				
39	F	40	5 Years	R. Cervical Rib	Right Cervical Rib				R	R			R	R			R	R	R			Yes	Relieved in 6 months. Cured in 18 months.
40	M	35	3 Years	Neuritis	Double Cervical Rib	2					2	2	2	2									
41	F	55	8 Years	L. Cervical Rib	Left Cervical Rib	L	L	L	L	L	L	L	L	L	L	L	L	L	I			Yes	Relieved in 2 months. Cured in 1 year.
42	M	36	2 Weeks	Traumatic Neuritis	Double Cervical Ribs		L	L	L	L													
43	M	32	$1\frac{1}{2}$ Year	Neuritis	Right Cervical Rib								R	R			R	R					Small short rib
44	M	$4\frac{1}{2}$			Double Cervical Ribs																		No symptoms
45	M	8			Double Cervical Ribs																		No symptoms
46	F	46	2 Years	Cervical Rib	Double Cervical Ribs	L	L	L	L	L	L	L	L	L	L	L	L	L	L	L	Yes		
47	M	36	2 Years	Neuritis	Double Cervical Ribs		R	R	R	R	R	R	R	R			R	R					
48	M	33	5 Years	Cervical Rib	Double Cervical Ribs	L	L	L	L	L	L	L	L	L	L	L	L	L				Yes	Improved in 4 months. Cured in 8 months
49	F	36	6 Years	Cervical Rib	Double Cervical Ribs	2	2	2	2	L	2	2	2	L	2	2	2	L	L	L			Symptoms most marked on L side but were bilateral
50	F	18	1 Year	L. Cervical Rib	Double Cervical Ribs			L	L	L		L	L	L		L	L	L	L			Yes	Relief in 3 months.
51	F	28	3 Months	Neuritis	Double Cervical Ribs	R	R	R	R	R	R	R	R	R	R	R	R	R					Cervical rib on R side longest
52	F	20			Double Cervical Ribs																		No symptoms
53	F	40	11 Years	R. Cervical Rib	Double Cervical Ribs	R	R	R	R	R	R	R	R	R	R	R	R	R	R	R	Yes	Yes	R. side operated. Circulation in hand improved in 1 month. Parasthesia gone in 1 month. Marked relief in 8 months.
54	F	61	15 Years	L. Cervical Rib	Double Cervical Ribs	L	L	L	L	L	L	L	L	L	L	L	L	L					Left rib longest
55	F	64	8 Years	L. Cervical Rib	Double Cervical Ribs								L	L			L	L					Left rib longest
56	F	50	9 Months	L. Neuritis	Double Cervical Ribs	L	L	L	L	L	2	2	2	2	2	2	2	2	2	L			Left rib longest. Atrophy and weakness bilateral.
57	F	34			Double Cervical Ribs																		No symptoms.
58	F	26	2 Months	R. Neuritis	Double Cervical Ribs	R	R	R			R						R						
59	M	45	2 Years	L. Cervical Rib	Double Cervical Ribs	L	L	L	L	L		L	L	L		L	L	L	L		Venous		Left rib longest
60	F	40	1 Year	Neuritis	Double Cervical Ribs	L	L	L	L	L	L	L	L	L	L	L	L	L	L				Left rib longest
61	F	38	6 Months	Neuritis	Left Cervical Rib	L	L	L	L		L	L	L	L									
62	F	59	5 Years	Neuritis	Double Cervical Ribs	2	2	2	2	2	2	2	2	2	2	2	2	2					Symptoms on both sides.
63	M	63	1 Year	Neuritis	Double Cervical Ribs		R	R			R	R			R	R							Right rib longest.
64	F	32			Left Cervical Rib																		Over 3 inches long. No symptoms.
65	F	31	1 Year	Neuritis	Double Cervical Ribs	2	2	2			2	2			2	2							Symptoms on both sides

Note.—The figure 2 in above tabulation is used to indicate bilateral findings.

LACERATIONS OF THE CERVIX.

By ISADOR W. KAHN, M.D.,

NEW YORK,

INSTRUCTOR IN GYNECOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

It is an established fact that every woman who faces the ordeal of maternity subjects herself to various traumata, either accidental or instrumental. Of these, lacerations of the cervix are by far the most frequent, in fact occurring so often as to be called universal. How rare indeed it is in routine postpartem examinations to find a cervix that has not undergone some degree of laceration. When we stop to consider the measures instituted to prevent such lacerations we find that they are practically nil. However, the degree of laceration depends upon well-established predisposing and concomitant exciting causes. I consider such conditions as rigid cervix or a previously diseased cervix, be it gonorrheal or otherwise, important predisposing causes. In addition I might mention faulty presentation of the presenting part; disproportion of the fetus and cervix; premature rupture of the membranes and faulty condition of the fetus.

Of the exciting causes there are several, each one a decided factor in producing a lacerated cervix. They are precipitate, or rapid second stage of labor; manual dilatation of the cervix to hasten labor; tedious labors; instrumentation. In a precipitate labor by energetic contractions of the uterus the fetal head is forced through the os before the cervix has had time to become softened and dilated and a lacerated cervix is the result. The injudicious use of pituitrin may be placed in this class. When cervical laceration follows a tedious labor it is due to the fact that the overlying portion of the cervix is incarcerated between the pelvis and the fetal head until it becomes edematous and thickened and finally gives way. Where instruments are employed, laceration of the cervix will usually result when forceps are applied with a cervix not fully dilated. When the cervix is dilated manually or instrumentally, it must be dilatable if we wish to avoid laceration.

Lacerations of the cervix may be classified as anterior and posterior; unilateral or bilateral; single, multiple, or stellate. They may be partial or complete. In the former the tear includes the cervical mucous membrane but does not reach the vaginal surface, while in the latter it does. When the laceration is unilateral it is most liable to occur in the line of the right oblique diameter of the pelvis and, due to the predominance of the left occipito-anterior position, the left lateral laceration is more frequent than the right. However bilateral lacerations are more frequent than unilateral and are by far more dangerous than anterior or posterior lacerations, as they open up the cellular tissues of the broad ligaments to infection. Stellate lacerations are more apt to be superficial and therefore less dangerous. In rare instances the tear may be in the median line and sometimes even circular, resulting in complete separation of the vaginal portion of the cervix from the uterus. Stellate lacerations are usually the result of repeated labors and are therefore found generally in multipara. They may be explained thus: Nature has tried to repair injuries to the cervix in previous labors by scar tissue, and in subsequent labor the previous sites of laceration are the strongest and so the tear occurs in a new area. When this is repeated several times we get a stellate laceration.

Symptoms and Signs.—These may be divided into early and late. The earliest manifestation of a lacerated cervix is hemorrhage occurring immediately after birth of the child. This hemorrhage may be profuse and dangerous where the laceration is extensive. Symptoms of shock may be evident. I therefore believe that a digital vaginal examination should be made under the strictest aseptic precautions directly after the expulsion or expression of the placenta in all cases of excessive bleeding, as very often this bleeding is said to be due to insufficient uterine contraction when really it is due to a lacerated cervix. The majority of these cases of cervical laceration are usually discovered in the course of a bimanual examination for some other pelvic complaint. These patients do not present any symptom or sign pathognomic or characteristic of a cervical laceration. The signs and symptoms are produced by the complications, or sequelæ, of these lacerations. Endometritis and subinvolution are frequent sequelæ, and from these occur disorders of menstruation, increased vaginal discharge, discomfort during walking and standing, sensation of weight and bearing down, and pain in the sacrum and iliac regions. These patients will complain of bleeding following coitus or following the introduction of a douche nozzle, evidence usually of a granulating cervix. Various nervous phenomena arise due to the fact that nerves are caught in cicatricial tissue formed in the angle of the tear. Reflex and general symptoms have often been overcome by proper treatment of a lacerated cervix. I place a lacerated cervix in the same category as the teeth, tonsil and appendix, for it is certainly a focus of infection with its rich supply of lymphatics. Finally we must not forget the rôle a lacerated cervix plays in the development of malignancy at some later date.

Diagnosis.—The finger and speculum afford the best means of diagnosis. I believe that a lacerated cervix, even though sometimes slight, is the beginning of many future pelvic disorders, and the sooner the diagnosis is made and proper remedial measures instituted the better will be our postpartem results. I believe that it should be a routine procedure to bring down the cervix and inspect it after the delivery of the placenta just as we do for perineal lacerations. I also believe that another speculum examination should be made during the puerperium. Such an examination would keep us informed as to the progress of a laceration and permit us to decide if surgical intervention be necessary. Having decided that a cervix requires surgical repair, it is my policy to permit the patient to reach a well advanced stage of uterine involution before attempting to repair the tear. During every subsequent speculum examination one should ascertain the amount of repair that has taken place if any; the extent of cicatrization; the condition of the cervix itself; the amount of cervical discharge; its color, odor, and other physical properties; and finally the extent, location and character of such laceration.

Treatment.—This may be divided into preventive and operative. By avoiding all measures instituted to unduly hasten the normal progress of labor much will have been done to avoid cervical lacerations. This includes meddlesome manipulations by manual or instrumental interference. The injudicious use of pituitrin should be discouraged. Precipitate labors should be retarded if possible. However, cases such as relative disproportion between the child and the cervix may render useless any precautions we may take.

Having decided that the cervix has been lacerated and badly enough to be repaired, what should be the proper method of procedure. Some obstetricians urge immediate closure of a torn cervix because it lessens the danger of infection from exposed surfaces, relieves the dread of future operation and prevents any ill effects due to delay. However, I am inclined to postpone repair of the cervix in the early puerperium. If the hemorrhage is troublesome it can be easily and safely controlled by the insertion of a tampon in the lateral vault of the vagina, using sterile gauze, as there is danger of absorption if iodoform gauze is used. This procedure is usually sufficient and rarely ever fails. Some, however, advocate the insertion of continuous catgut sutures where bleeding is profuse. I am against the insertion of ligatures to control postpartum cervical bleeding. Sutures inserted into a torn cervix to control bleeding increase the danger of puerperal infection and their insertion is always difficult. I am inclined to favor the intermediate operation, which is usually done about the ninth day pastpartum. Following labor the cervix is thinned out and so it is difficult to determine the extent of the lesion; sutures placed in a relaxed cervix will not be tight enough at the end of 36 to 48 hours to close the wound; to place these sutures properly it is necessary to drag the cervix into view by bullet forceps; the woman very often is in an exhausted state after a difficult labor, and it would be folly to subject her to a surgical operation.

Where a cervix is badly lacerated it is usually accompanied by a laceration of the perineum of varying degree, and here especially I believe in delaying operation, as it permits the structures to regain to some degree their normal outlines. If there has been any doubt about our asepsis it will have manifested itself before the torn tissues have been closed. Our operation so postponed will promote normal involution and lessen the dangers of endometritis. I do not believe in repairing small tears as they usually heal spontaneously. Sutures placed in small tears impair uterine and cervical drainage and increase the dangers of sequelæ. Strict asepsis in obstetric practice promotes the repair of these small injuries without operation.

Unfortunately most cases of laceration of the cervix are not recognized or brought to the attention of the gynecologist until pathological changes in the female pelvic organs have impaired the health of the patient. An imperative requirement of those practicing obstetrics should be a routine examination of the pelvic organs in the second or third week postpartum to determine the existence of any pathological condition requiring attention. This would avoid instituting measures for the relief of sequelæ arising from such lacerations. The secondary operation should be done about the third month postpartum, for by that time the cervix will have regained its normal form as far as the injury will permit. In any case the secondary operation will have to be preceded by local treatment for the relief of such conditions as the engorgement of cervix or fundus; obstruction of cervical glands, and reduction of infection. Every secondary operation should be preceded by a thorough and systematic curretage for the relief of the accompanying endometritis. The dilatation of the cervix permits of the escape of the products of endometrial infection and very often affords a cure for the accompanying pelvic inflammation. Thickening or adhesions in the pelvis of the chronic nonpurulent variety may be due to extension from the uterine endometrium, which in turn is due to a lacerated cervix.

Conclusions.—It should be the duty of every physician doing obstetrics to employ every precaution to prevent lacerations of the cervix as he does the perineum. We stand ready to guard the exposed perineum in a tedious or difficult labor but forget about the hidden cervix. Where a laceration has occurred remedial measures should be instituted as soon as possible. Every lacerated cervix starts the owner on the road to chronic invalidism due to complications and sequelæ. Routine vaginal examinations should be made after delivery of the placenta to determine the degree of laceration, if any, and weekly thereafter to determine the progress of such condition.

Medicolegal Notes.

Workmen's Compensation Acts and Physician's Rights of Action Against Employers.—The Minnesota Workmen's Compensation Act, in force in 1917, did not, it is held, give to a physician or surgeon who furnished medical treatment to an injured employee a right of action for the value thereof against an employer who had not requested or consented to the furnishing of the treatment by such physician or surgeon. The law, as regards an injury occurring in 1917, "afforded a remedy only in one proceeding and that to be instituted by the injured employee alone, if alive, or by his dependents if death resulted. Some compensation statutes like those of California and New York make provisions for liens to physicians upon the compensation adjudged, and specify how to secure them. Pacific Coast Casualty Co. v. Pillsbury, 171 Cal. 319; Bossert & Sons v. Piel Bros., 182 N. Y. Supp. 620. In other States the law prescribes different ways in which the one furnishing the injured employee with medical necessities may assert his claim against the employer. Under the Pennsylvania law, which imposes the duty upon the employer to furnish medical treatment at whatever cost for the first fourteen days after the accident, the court held that where the injured employee had been taken to the plaintiff for treatment with the defendant's consent the plaintiff had a cause of action against the latter upon an implied contract. Trustees of State Hospital v. Lehigh Valley Coal Co., 267 Pa. 474, 110 Atl. 255. Here there is no finding that Finch went to plaintiff for treatment with defendant's knowledge or consent, and hence there is no cause of action upon implied contract." Nor in any event can an employer be held liable for such treatment if he neither consented thereto nor refused or was unable to furnish needed treatment. Even were liability to suit conceded, it could not be maintained if brought after the time specified in the act. The court did not say what effect, if any, the amendment of 1921 to the Minnesota act would have.—Beach v. Bender, Minnesota Supreme Court, 182 N. W. 607.

EXTRACARDIAC MURMURS.

EXTRACARDIAC murmurs are of two kinds: some are seated in the visceral envelope of the heart and should be qualified pericardial; the others arise in the pulmonary apparatus but should be classed with the former on account of the similarity they offer to heart murmurs and also because they are produced by the movements of the heart. Pericardial friction is very common, being moist, dry, soft or rough, and can be heard especially at the time of systole. Its rhythm is not regular, therein completely differing from souffles. It remains localized, while its intensity seems to be proportional with the extent of contact existing between the two layers of the pericardium. Usually it is accompanied by a thrill readily detected by the hand. Other murmurs may simulate it, such as a pleural thrill which can be distinguished by its synchronism with the respiratory movements, excepting in those rare instances where it results from the heart beats. Confusion of pericardial friction sounds with murmurs is not always easy to avoid when the former take on a sibilant character and are not limited to a small area. However, pericardial friction-sounds have no rhythm and are superficial and very limited in extent; they disappear when a fluid effusion occurs and reappear when the fluid has been absorbed, and are then usually rougher and more intense than at the onset.

Extracardiac sounds of the second type are seated in the pleura and lungs. The abnormal sounds of the pleural cavity produced by the heart movements are the better known. They are generally preceded or accompanied by sharp thoracic pain, are very superficial, and are heard over the midpericardial region at a point quite far from the sternum. They accompany diastole much more rarely than do true pericardial friction sounds and almost invariably coincide with the ventricular systole. Rhythmical pleural friction sounds due to the heart beats are not generally limited to the pericardial region, but are heard elsewhere. In many cases their appearance is followed by a fluid pleural effusion, when they disappear to be again heard when the liquid is absorbed. Briefly, when friction sounds synchronous with ventricular contraction and having these characters are heard without any symptom of pericarditis, pleurisy should be suspected, and this diagnosis cannot be doubted if the respiratory movements, especially during deep inspiration, give rise to friction sounds.

Certain sounds produced in a diseased lung by the heart beats were long ago suspected by Laennec, but their nature has been definitely recognized only since the work of Potain and Choyau. They almost always coincide with morbid changes due to phthisis, especially cavity formation and pleuropericardial adhesions capable of retaining portions of diseased pulmonary parenchyma in front of the heart area. To bring them out and to distinguish them from those produced by the respiration, the patient should stop breathing. They consist of moist and rattling sounds.

Sounds due to systolic and diastolic cardiac and vascular beats, seated in a healthy portion of the lungs, were mentioned by Laennec, but the sounds to which he referred do not belong to those about to be considered. He met with them in chronic bronchitis and phthisis. Laennec also described under the term of pulsatile pulmonary crepitation a sound similar to a crepitant râle produced by the heart's action compressing the lungs, at each ventricular systole, during inspiration.

Woillez has described a pulmonary souffle occurring with the aortic diastole, very similar in type to the cardiac souffles of chlorosis. It almost always coincides with ventricular systole, exceptionally with diastole, and ordinarily only during expiration. When present in cardiac hypertrophy it can be heard during both respiratory phases. It is a matter of some difficulty to explain its mechanism, but Potain is inclined to believe that it is inspiratory and develops as follows: At the time of ventricular systole, the heart decreasing in some of its diameters, suddenly causes a vacuum in front of a certain number of pulmonary cells already collapsed; air then rushes into these alveolæ, producing a sound of partial inspiration having the character of a souffle. Choyau says that this explanation holds only in some exceptional cases in which the souffle coincides with the second cardiac sound, while in all others—which are far more numerous—the sound is due to partial expiration rendered sibilant by the sudden cardiac shock. However this may be, what gives the character of a souffle is the rapidity of penetration of air into a limited area of healthy lung parenchyma interposed between the thoracic wall, the heart, and the large vessels. If the sound is ordinarily produced only during expiration it is because, the thoracic walls being then much nearer the circulatory center than during inspiration, compression of the lung by the heart is brought to its maximum. In the same way cardiac hypertrophy, when considerable, produces a sufficient pulmonary compression to give rise to a sound even during inspiration and thus produces an uninterrupted souffle.

Kuessner has divided extracardiac morbid sounds

arising in the respiratory apparatus into two principal groups: (1) Those simulating endocardial sounds and which, in reality, are pulmonary soufflés, and (2) those which simulate pericardial friction sounds due to pleural exudates. Both sounds are seated in the tongue of the upper lobe of the left lung, described by Luschka, which sometimes covers the apex of the heart. They appear, disappear, and vary in character and intensity without any appreciable cause and are not related to any particular movement of the heart, but they are markedly modified by the respiratory movements.

THE CYTOLOGY OF HYDRARTHROSIS.

THE hydrarthroses form a disparate and nonhomogeneous group of lesions. Hydrarthroses of gonorrheal or tuberculous etiology are specific lesions, so that only the cytology of traumatic and the so-called essential hydrarthroses—for want of a better name and indicating our ignorance of the subject—need be considered; but to these may be added those of hydrarthrosis resulting from a neoplasm in the bone near the joint. At present, on account of the numerous arthrocenteses currently done, the cytology of traumatic hydrarthrosis has been fairly well worked out. During the first few weeks of the process the appearance of the fluid content offers one of two types. Sometimes it is colorless, in which case it is a true hydrarthrosis; at other times it is tinted pink and is therefore rather a hemo-hydrarthrosis, but from the clinical viewpoint this can be included among hydrarthroses. In the first type, there is simply a mechanical irritation and Mauclaire and Julliard have shown that in them nothing but endothelial cells are present in the fluid. In the second type, red blood corpuscles represent the majority of elements, being about 90 per cent., but in some cases they may represent only about 50 per cent. In the latter circumstance a very slight hemorrhage has taken place in the joint at the same time as the irritation.

After a few months have passed, hydrarthroses have a cytological formula which is about constant; the red blood corpuscles form the major part of the elements, while lymphocytes represent a good part of the other elements present. This seems to have been quite conclusively shown by Dopter, Tanton, Thirion, and others. Now, it is known that clinically hydrarthroses have a very different evolution from one case to another. Some are recovered from in a few days, but these are very exceptional; others, on the contrary, last for years, although this cannot be explained by the patient's general health, nor can any local cause be found preventing recovery. Consequently, perhaps, it can be admitted that certain hydrarthroses characterized simply by a shedding of the endothelial cells in the joint are recovered from quickly, while others, in which a trifling intraarticular hemorrhage has taken place, are obstinate to treatment, and are painful, accompanied by chronic irritation made evident by the presence of numerous lymphocytes. The cause of this slight hemorrhage may be in some cases a tear of the ligaments, as some patients complain of pain over the internal lateral ligament especially.

The hydrarthroses of unknown cause comprise an extremely varied lot of cases. The hydrarthrosis may be constant or recurring. In one case of the latter form, Dopter and Tanton found only lymphocytes, and in another an equal proportion of lymphocytes and polynuclears. But among the hydrarthroses of unknown etiology a variety has been described by Thirion, characterized by the absence of any cell elements that can be detected by cytoscopy. One case was in a man with pneumonia with a very large knee joint containing fluid, which had been present for years and was troublesome only after long walks. After defervescence of the pneumonia, 10 c.c. of fluid was withdrawn from joint; it formed no deposit whatsoever. Two other cases gave the same history with the same cytological results. In all three the fluid was viscid, resembling normal synovia, so that it may be thought that these cases represented an excessive secretion of this fluid and absence of absorption of the excess.

In one case of hydrarthrosis, an osteosarcoma of the lower end of the femur, the neoplastic granulations had perforated the cartilage and penetrated the joint, which was greatly distended with fluid; 50 c.c. of the fluid was withdrawn and was found to coagulate very rapidly. After defibrination it was examined, and numerous lymphocytes and red blood corpuscles were found. In spite of very many examinations, no sarcomatous element could be detected. The growth in the femur had produced an histologically hemorrhagic fluid such as happens in cases of sarcoma extending to the pleura.

Briefly put, traumatic hydrarthroses contain either endothelial cells or red blood corpuscles with lymphocytes. The predominance of endothelial cells indicates a recent irritation of the joint of little gravity. A predominance of red blood corpuscles should make the prognosis more reserved. Simple traumatic hydrarthroses do not present polynucleosis. Nontraumatic hydrarthroses may contain lymphocytes or polynuclears; sometimes the process seems to be due to a simple excess of synovial fluid in the joint, and no trace of figured elements can be discovered.

CUTANEOUS DIPHTHERIA.

THE World War has brought this subject before the medical profession anew. German surgeons saw wound localization in one-fifth of their diphtheria cases, and in only about 25 per cent. of them was faucial diphtheria also present. The frequency of these wound infections may easily be exaggerated, but certainly in any suspicious or atypical ulceration the secretions should be examined for the

bacillus of the disease. In summing up his long narration of a personal case in a man of twenty-seven years, Winkler (*Schweizerische medizinische Wochenschrift*, April 21, 1921, li, 16) emphasizes that the general condition was excellent at the time of the outbreak; that two sharply bordered ulcers with a grayish-white deposit appeared on the scrotum with larger and crustous ulcers on the right thigh and apparent furunculosis of the right hip region. These manifestations were followed by the appearance of faucial and nasal diphtheria. The disease-toxins caused a renal lesion—albuminuria and white blood cells in the urine. The pathogenesis was probably as follows: The virus was doubtless conveyed by the nails to the delicate skin of the scrotum, which was slightly macerated by dancing or cycling. From the initial focus the thigh was infected and two days later there was the first appearance of sore throat. Three other members of the family had a mild angina, which in at least one case was associated with the diphtheria bacillus. The family were butchers by trade, but the author is skeptical concerning the transmission of animal diphtheria to man, and the origin of the episode remains unsolved. Those interested in cutaneous diphtheria may read the magistral account by Trousseau, who had unusual opportunities for studying it. He witnessed one murderous epidemic in which the cutaneous location was greatly feared, since it often meant death to old as well as young. He said of it that it appeared on blistered surfaces, in the cutaneous folds of fat children, in herpes vesicles, rhagades of the breast, incised wounds, scrotal excoriations, and, in short, on any area divested of epidermis and subject to irritation.

In our own day the affection is limited almost wholly to children, especially those with the so-called scrofulous and exudative diatheses. Serum injection does not always prevent death from paralysis of the heart. Landé of Göttingen, who saw forty-four cases, states that the retroauricular fold was a favorite seat of cutaneous diphtheria. The typical diphtheritic ulcer he describes as follows: The epidermis is destroyed; the floor of the ulcer is the derma or papillæ of the corium; the margin is dentate and more or less infiltrated, at times like a wall with steep incline; the surrounding skin is reddened; there is a so-called false membrane on the base of the ulcer, of a grayish white or grayish yellow color, which comes away with difficulty and bloodily. The size of these ulcers varies greatly—from that of a pinhead to larger than a silver dollar. The membrane may be absent, or present only as a thin veil, but in many cases there is formation of a thick crust. The general picture has simulated impetigo, varicella, pemphigus, ecthyma, etc. Secondary phlegmon may develop in certain cases, as in diphtheria of the navel stump, causing fatal peritonitis. A diphtheritic felon has been described, and Kyrle has reported a case of chronic diphtheritic ulcer without implication of the general health.

The preceding pictures do not include actual wound diphtheria in which definite war wounds became infected with the bacillus. Aside from frank cases with severe and fatal termination there was an entire series of cases of wounds, smears from which showed the bacillus without clinical diphtheria. One German surgeon, Weinert, alone saw 200 cases of the latter, while of about 500 miscellaneous wounds in another clinic nearly 60 per cent. showed the bacillus on smears.

OSTEOMALACIA.

THIS affection has assumed new importance since the war because of the evident existence of a hunger type of the malady, because of the relationship with late rachitis and many bone deformities now classed under the latter, because of the advance of our knowledge of radiographic diagnosis, and of course by reason of the close relationship between osteomalacia and endocrine pathology. Hence, the article on this affection and its congeners by Schlesinger in the *Wiener klinische Wochenschrift* for May 5, 1921, xxxiv, 18, should be of timely interest. The term osteomalacia according to this author now denotes a group of diseases which show one trait in common—softening of the bones which may readily be cut, fragility, decalcification in places, etc. The skeleton is not uniformly involved in this process. First should be mentioned puerperal osteomalacia, a condition much more common than has been supposed. It shows a tendency to regional cumulation in certain localities. The initial symptoms comprise algias, so that the affection is often confused with neuralgias and rheumatism. There may be tenderness over the sternum, ribs, spine, or pelvis. A symptom of great significance is the adductor tension or spasm when the thighs are sharply abducted. Precocious paresis of the psoas is seen in stair climbing. The symptoms of the fully developed condition are sufficiently well known. Senile osteomalacia is seen after the close of the menopause and is a progressive affection. Paradoxically it cannot be brought in close association with abolition of the ovarian function. It is often associated with angiosclerosis of the arteries of the lower extremities. The condition is distinct from osteoporosis, but differentiation is by no means easy at times.

The osteomalacia of psychoses is more than a coincidence. It is very far from rare and attacks men as well as women. It is very difficult to recognize, for the numerous pains complained of are commonly regarded as psychogenic. Hunger osteomalacia has been known only since 1919, when it occurred in Austria in an outbreak of wide incidence. The initial symptoms were tenderness and spontaneous pains over the lower ribs and at times over the cranial bones. It stood in some close relationship with hunger tetany. In incomplete form hunger osteomalacia gave origin to a number of hitherto undescribed clinical pictures in the young. Here belong spontaneous fractures and certain painful local affections involving the spine, hips, sac-

rum, etc. Hunger osteomalacia was ascribed to general lack of food and lack of fats in particular. In regard to endocrine motivation the author mentions the frequent find of hyperplasia of the parathyroids and there is considerable evidence to suggest that osteomalacia is a pluriglandular syndrome. Under diagnosis, multiple bone tumors from metastasis may be excluded by the absence of albumosuria, absence of a primary focus in the breast, thyroid, etc., and especially by the *x*-ray. Paget's bone disease may also be excluded by the latter resource. The treatment of osteomalacia comprises phosphorus in codliver oil, soluble calcium salts, and, in cases of underfeeding, an appropriate diet.

The Treatment of Tuberculosis by Sodium Morrhuate.

For long in India and elsewhere chaulmoogra oil has enjoyed a high reputation in the treatment of leprosy. Dr. Victor Heiser by compulsory segregation and by the administration of chaulmoogra oil diminished greatly the incidence of the disease in the Philippines. In a paper read before the Section of Therapeutics and Pharmacology at the Royal Society of Medicine on April 19, 1921, Sir Leonard Rogers after relating his successful experiences with the gynocardate and chaulmoograte of sodium by intravenous injection in the treatment of leprosy, suggested an analogous method for combating tuberculosis. As for the use of oils of this nature in tuberculosis, Rogers says that the efficiency of sodium morrhuate, which he tested with favorable results in 1917, both subcutaneously and intravenously, in his opinion, justifies the publication of the method for trial by others and in preference to the use of tuberculin. The results recently shown in pulmonary cases were not so satisfactory as in glandular tuberculosis and lupus, in which the drug appeared to have a selective action, and for the former he advised treatment by sodium morrhuate combined with streptococcal vaccine derived from the organisms secondarily infecting the sputum. Experimental study of the gynocardate and morrhuate products in the laboratory had shown the destructive effect of the former on acid-fast bacilli, the addition of 1 per cent. sodium gynocardate preventing their growth on solid media. On the other hand, the morrhuates had no effect on cultures *in vitro;* when infected intravenously, however, they caused breaking up of the bacilli, a process which had been demonstrated in microscopical section of the leprous lesions. So far as this treatment of tuberculosis is concerned, it is still in the experimental stage, but experiments in this direction are sufficiently encouraging to arouse and foster the hope that, at any rate, the glandular forms of tuberculosis, for which sodium morrhuate appears to exhibit a selective action, should be benefited by its administration.

Diffusion Through the Vagus Nerve of Poisons Taken by the Mouth.

The vagus nerve is often involved more or less in organic affections of the stomach. In ulcer and especially ulcus callosum of the lesser curvature, as well as in certain cases of cancer, there may be a vagus neuritis. From the peripheral filaments the disease ascends along the nerve fibers until the trunk is reached. In studying this phenomenon, Loeper, Forestier and Tonnet made a number of experiments with toxic substances—potassium ferrocyanide, formol, and tetanus toxin, substances which may be demonstrated by histochemical or biological tests. (*Progrès Médical,* April 30, 1921, xlix, 18). In young fasting dogs the pylorus was ligated and 60 c.c. of the 20 per cent. solution of ferrocyanide introduced into the stomach. Absorption was shown by the elimination of the drug in the urine but the histochemical test of the tissues with hydrochloric acid and perchloride of iron proved negative. When formol was used to the extent of 30 c.c. of 15 per cent. aqueous solution the result was also negative, but the substitution of a glycerine solution, after scratching the mucosa with a needle, gave a positive result, as shown by the rosaniline bisulphite test. In the absence of exact information on the matter we have to conclude that these histochemical tests were made in connection with fibers of the vagus. The tetanus toxin was introduced into the stomach like the other substances—20 c.c. of a 1 to 2 per cent. solution after ligation of the pylorus. Here a histochemical demonstration was of course out of the question. It was long ago shown by Vincent that the stomach mucosa and juices are able to neutralize the local action of the toxin and prevent its absorption. The authors therefore took the precaution to scratch the stomach mucosa with the needle as above mentioned. The left vagus was then excised, triturated into a pulp, and injected into the right forefoot of a guinea pig. The second day showed a paresis of this member, followed on the ensuing day by full paralysis and contracture of the same. The sciatic of the same dog used as control gave a negative result. So far as the research has gone it seems assured that at least two classes of substances, aldehydes and toxins, are able to traverse minimal lesions of the gastric mucosa and became incorporated incidentally in the distribution of the vagus nerve. It is, therefore, possible that in the pathological stomach certain toxic substances may also be able to interfere with the innervation of the vagus nerve in a like manner.

Impalement Injuries.

These lesions are relatively rare, and we do not recall any large material even in collected cases. It is therefore somewhat of a coincidence to find a report of 7 cases in the current number of the *Journal d'Urologie* (xl, 4) and another of 5 in the *Upsala Läkareförenings Handlingar* for June 8, 1921, xxvi, 3-4. The longer series is reported by Ferron under the title of wounds of the perineum, all but one occurring in males. Four patients died of the injury. They had been operated on, but too late to save life. The fatal result seems to have been due to wounds of the intestine. Of those who escaped death one suffered from a perforated bladder while the other two sustained a lesion of the urethra. So far as the external wound is concerned all the cases were of a single type—lacerated, profusely bleeding wound of the perineum. The paper,

while long, is wholly technical and the author attempts no analysis of his cases. The other reporter is Häggstrom of Upsala, the assistant of Petrén. Four cases are given in the first contribution, followed by a separate description of a belated fifth case. There is a notable difference between the Scandinavian and French cases for the former occurred in children and adolescents, and of the five, two were female. The material of Ferron comprises three elderly and two young men, one adolescent, and a little girl. Of the seven cases of Ferron, five were intraperitoneal, all ending fatally but one. Of the five Scandinavian cases, two were intraperitoneal, but all five recovered, in marked contrast with the mortality in the French series. Quite unlike the latter, in which the anus and rectum seem to have been spared, the Upsala series presented but two cases of perineal wound, the sharp object having in the other three cases entered the pelvis through the anus.

News of the Week.

Infantile Paralysis in New York State.—According to figures made public on September 9, there had been reported to the New York State Department of Health from July 1 to that date 241 cases of infantile paralysis with 21 deaths. It is probable, however, that these figures do not represent the entire mortality from this cause. The total number of cases of infantile paralysis reported to the New York City Health Department during this period was 78, making a total of 319 for the entire State. Fifty-eight cases have been reported from Utica.

Source of Typhoid Fever Epidemic Discovered.—The typhoid fever epidemic in Monmouth and Burlington counties, N. J., has been traced by the State Department of Health to chicken salad served at a church harvest home festival in Jacobstown, July 27. Up to September 8, there have been 200 cases reported in 116 homes in twenty-three different communities, all traced to the harvest festival. This is the most widespread and virulent epidemic of typhoid fever that has occurred in New Jersey for many years. Patients have been discovered on certain dairy farms from which milk is shipped over a wide area. The health authorities have accordingly stopped the shipment of milk from such farms.

Society for Cinematographic Instruction.—This society, in New York City, has devoted the past eighteen months to experimental work at hospitals and laboratories in order definitely to ascertain the applicability of the motion picture to the study of medicine, surgery, and dentistry, and through processes which have been evolved it is now possible to record accurately and permanently every detail of any minor or major surgical operation. Having established this fact, it is the aim and intention of the society to work out various courses of study by means of cinematography, and to establish a central cinematographic library in New York City. This library will be equipped for private and group study, while members and institutions at a distance may either rent or purchase at a nominal charge, duplicate copies of any of the subjects in the main library. At the present time an exchange arrangement is being negotiated with the profession in a number of the European countries where such cinematographic work is being done. Any physician, surgeon, or dentist in good standing is eligible to membership in the society. Monthly meetings will be held at which will be shown the latest work in its courses, and research work will be pursued continuously. Dr. James S. Edlin of New York is president of the society.

New Hospital Nears Completion.—The Fifth Avenue Hospital, New York, located on Fifth Avenue between 105th and 106th Streets, is rapidly progressing toward completion. Of a total of $3,000,000 for the building fund only $750,000 remains to be subscribed. An endowment fund of $1,000,000 has been provided which will insure maintenance after completion. This will be the first wardless hospital in the world, and is designed especially for persons who have not enough money to pay for private care and who do not wish to accept charity.

Connecticut Psychopathic Hospital.—Under the auspices of the Yale Medical School, the State of Connecticut and the Rockefeller Foundation will unite to finance a proposed Connecticut Psychopathic Hospital. The Rockefeller Foundation will contribute $500,000, the State probably the same amount, while the share and part of Yale in the transaction have not yet been determined. The hospital building will be erected by that State grant, the Rockefeller Foundation will supply the salaries for the teaching staff, while Yale may supply the clinical quarters and other costs. There will be a close connection between the Psychopathic Hospital and the New Haven General Hospital. Dr. Paul Waterman of Hartford is Chairman of the Commission.

Dr. James G. Fickel, who has practised medicine for nearly fifty years in Carlisle, Pa., retired from active practice on September 1.

Dr. James A. Waterman of Breckenridge, Mo., has been named penitentiary physician of Jefferson City to succeed Dr. W. A. Clark.

The American Public Health Association will hold its semi-centennial celebration in New York City, November 8-18, 1921. There will be four phases of the celebration: (*a*) Scientific sessions will be held November 14-18. (*b*) A health institute will be conducted during the week preceding the convention proper, November 8-12, which will consist in organized demonstrations of the various types of public health activities in New York and its environs. (*c*) Dr. Stephen Smith, the founder and first president of the Association, who is now in his 99th year, will be the guest of honor at a banquet to celebrate his approaching centennial and the semi-centennial of the Association. (*d*) An historical jubilee volume, entitled "Fifty Years of Public Health," will be published about October 1. There will be articles by seventeen authors, relating to the accomplishments and present status of each of the important branches of public health, and presenting a general history of public health from the earliest days to the present. Information regarding the celebration may be had upon addressing the Association at 370 Seventh Avenue, New York City.

Promoter of Fraudulent Tuberculosis Cure

Prosecuted.—The New York City Department of Health brought action some time ago against a physician of this city for violation of section 118 of the Sanitary Code, which pertains to fraudulent representation concerning treatment. Evidence was presented at the trial which showed conclusively that the accused had claimed that a preparation made by him was a specific cure for tuberculosis. These claims were proven to be fraudulent and, as a result, a $500 fine was imposed by the court. The case was of somewhat more than usual interest because of the difficulty of obtaining a sample of the preparation for analysis, as the man insisted on administering it himself, believing that in so doing he was safe from prosecution because of lack of evidence. However, a sample was finally secured for analysis, which showed that the preparation was a shotgun mixture of a great many common pharmaceuticals.

Medical Society Elections.—THE MEDICAL SOCIETY OF DELAWARE at its 132nd annual session held in Rehoboth, August 14-16, 1921, elected the following officers for the ensuing year: *President*, Dr. J. W. James, Dover; *First Vice-President*, Dr. James M. Martin, Magnolia; *Second Vice-President*, Dr. John Ball, Elsmere; *Secretary*, Dr. W. O. LaMotte, Wilmington; *Treasurer*, Dr. S. C. Rumford, Wilmington.

THE ALBERTA MEDICAL ASSOCIATION, at its meeting held in Calgary, Alta., August 17, 1921, elected the following officers for the ensuing year: *President*, Dr. A. E. Archer, Lamont; *First Vice-President*, Dr. A. Anderson, Edmonton; *Second Vice-President*, Dr. William McKenzie, Red Deer; *Secretary*, Dr. Hepburn, Edmonton; *Treasurer*, Dr. T. J. Costello, Calgary.

Obituary Notes.—Dr. WALTER W. PARMALEE of Auburn, Maine, died following a surgical operation on September 2, at the age of forty-seven years. He was graduated from the University of Vermont Medical College in 1909.

Dr. FREDERICK NORMAN SWIFT, a graduate of Long Island College Hospital, Brooklyn, in 1896, died at his home in West Chazy, N. Y., on August 10.

Dr. STANLEY HEWITT HAYNES of Minneapolis., Minn., died in a local hospital following an operation on August 8, at the age of twenty-eight years. He was graduated from Rush Medical College in 1919.

Dr. ALBERT W. GREEN of Utica, N. Y., a graduate of the College of Physicians and Surgeons, Baltimore, in 1884, died from the effects of a paralytic stroke on August 17, at the age of sixty-eight years.

Dr. WILLIAM F. ROSS of Booneville, Ark., a retired physician, died on August 9, at the age of sixty years.

Dr. WILLIAM M. KENNISTON of Exeter, N. H., died of heart disease in Skowhegan on August 18, at the age of fifty-one years. He was graduated from Bowdoin Medical School in 1895.

Dr. M. R. WAGGONER, a practitioner of medicine of De Witt, Ia., for sixty-five years, died on August 11, at the age of eighty-three years. He was graduated from the Hahnemann Medical College and Hospital Chicago, in 1871.

Dr. JOHN M. BOICE of Sistersville, W. Va., a graduate of the Medical College of Ohio in 1878, died suddenly in August 12, at the age of sixty-five years.

Dr. JOHN A. DUNCAN of Havre, Mont., a graduate of the University of Toronto Faculty of Medicine in 1904, died suddenly of heart disease on August 10, at the age of forty-three years.

Dr. HENRY A. VEAZIE of New Orleans, La., well known for his work and writings on yellow fever, died after a lingering illness in a local hospital on August 11, at the age of sixty-six years. He was graduated from Tulane University School of Medicine in 1876, and for many years has been a member of the visiting staff of Charity Hospital.

Dr. ROBERT EUGENE BERING of San Francisco, Cal., a graduate of Tulane University, New Orleans, La., in 1895, died of paralysis at Long Beach, Cal. He was for fifteen years superintendent of the Bering Senatorium in San Francisco and a former member of the Standard Medical Faculty.

Dr. F. D. VANDERHOOF of Phelps, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1864, and said to be the youngest surgeon in the Civil War, died on July 29, at the age of seventy-eight years. For several years he served the town of Phelps as health officer.

Dr. NATHANIEL GREEN STANTON, the oldest practicing physician in Newport, R. I., died suddenly on July 2, at the age of eighty-five years. He was graduated from Harvard University in 1866.

Dr. LESTER BURNSIDE LEGRO of Haverhill, Mass., died of diabetes on August 18, at the age of fifty-six years. He was graduated from the Baltimore Medical College in 1905, and was a member of the American Medical Association and the Massachusetts Medical Society.

Dr. HENRY WINCHESTER SAWTELLE of Washington, D. C., after an illness of five years, died in a local hospital on August 19, at the age of eighty years. He was graduated from Georgetown University in 1868, and was appointed an Assistant Surgeon in the U. S. Marine Hospital Service in 1873. He was promoted to the grade of Surgeon in 1879, served at various Marine Hospitals in the United States, and was retired from the service in 1906. He was a member of the American Medical Association, the State Medical Association of Maine, the Association of Military Surgeons of the United States, the Detroit Academy of Medicine, and the Southern Medical Association.

Dr. JOHN S. SAUVELLE of New York, a graduate of the College of Physicians and Surgeons, New York, in 1889, died on August 28. He was for many years consultant to the French Hospital.

Dr. WARREN BLANCHARD CHAPIN, a graduate of New York University Medical School in 1888, died at his home in New York City on August 29.

Dr. GEORGE VICKERS PRICE, a retired physician of Brooklyn, N. Y., died of cerebral hemorrhage on August 30, at the age of sixty-five years. He was graduated from New York University Medical College in 1885.

Dr. ALEXANDER MARCY, Sr., for many years a practising physician of Camden, N. J., died at his summer home at Cape May on August 18, at the age of eighty-four years. He was graduated from the University of Pennsylvania school of Medicine in 1861.

Dr. ARTHUR G. THOMPSON of Pine Bluff, Ark., a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1880, died suddenly on August 18, at the age of seventy years.

Dr. LEWIS C. PAGE of Honey Grove, Tex., a graduate of Rush Medical College in 1870 died on August 20, at the age of 76 years.

Dr. HENRY RICH HIGGINS, a graduate of Boston University School of Medicine in 1883, died at his home in Boston on August 23, at the age of seventy-six years.

Dr. CHARLES A. STONE of Mason City, Ill., died on August 20, at the age of fifty-two years. He was graduated from Rush Medical College in 1894, and served for a terms as mayor of Mason City.

Dr. SAMUEL BURTON MCGARRY of Joice, Ia., a graduate of Drake University College of Medicine, Des Moines, in 1903, died in a hospital in Mason City, Ill., on August 20, at the age of forty-eight years.

Dr. ERNEST PIERRE DUPRE of Paris, an officer of the French Academy of Medicine, died on September 2, at the age of fifty-nine years. He was widely known for his writings on pathology and on nervous and mental diseases.

Dr. FRANK P. SMITHSON of Forest Hill, Md., died of paralysis in a local hospital, on August 12, at the age of sixty-nine years. He was graduated from the University of Maryland School of Medicine in 1880.

Dr. EBENEZER ALDEN DYER of Whitman, Mass., a graduate of Bellevue Hospital Medical College, New York, in 1882, died after a lingering illness, on August 22, at the age of sixty-three years.

Dr. FRANCIS JAMES DRAKE of Phillipsburg, Pa., a graduate of the University of Pennsylvania School of Medicine in 1900, died in a local hospital on August 26, at the age of forty-nine years.

Dr. AMERIC GEORGIO D'AMICO of Somerville, N. J., a graduate of the University and Bellevue Hospital Medical College in 1919, was instantly killed when his automobile was struck by a locomotive near Somerville, on August 28. He was twenty-six years of age.

Dr. ROBERT B. CAREY, of West Chester, Pa., a graduate of the University of Michigan Medical School in 1871, died after a prolonged illness, on September 2, at the age of seventy-nine years.

Dr. GERTRUDE A. G. BISHOP of Brooklyn, a graduate of the New York College and Hospital for Women in 1877, died on September 5, at the age of eighty-three years. She was at one time resident physician of Wellesley College, and for twenty years was a director of the Woman's Health Protective Association of Brooklyn.

Dr. FREDERICK S. CRUM of Newark, N. J., assistant statistician of the Prudential Insurance Company, was accidentally drowned near Oakland, Me., on September 2. He received the degree of Ph.D. from Cornell University in 1897, and for many years was a member of the Newark Board of Health. He was forty-nine years of age.

Dr. CHARLES H. SMITH of Linglestown, Pa., died from the effects of a stroke of apoplexy on September 2, at the age of seventy years. He was graduated from the University of Pennsylvania Medical School in 1872, and was for many years Commissioner of his county.

Correspondence.

THE EPIDEMIC OF POLIOMYELITIS IN THE CITY OF NEW YORK.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—During the last ten days poliomyelitis has assumed a truly epidemic character, the increase in the cases apparently being the result of the return of a large number of children from the different summer resorts. The disease being much milder in character than in 1916, undoubtedly a great many cases are escaping observation. The prodromic stage is very indefinite, consisting of slight fatigue, anorexia, and irritability, and is rapidly followed by vomiting, rise of temperature and pulse-rate, rigidity of the neck, especially on bending the head toward the sternum, muscular tremor or jerking, more or less marked drowsiness, and pronounced irritability when disturbed. The patients complain of pain only when handled. In one of our cases, in an infant eight months old, the onset of the disease was accompanied by convulsions, and in another case, a boy four years old, by transitory diplopia. The paralysis makes its appearance within about forty-eight hours of the onset of the disease. Facial paralysis is especially common in this epidemic and abducens and glossopharyngeal paralysis is not uncommon. In only one of our cases were the respiratory muscles affected. In several of our cases, instead of frank paralysis, only marked ataxia was noted, which symptom, by the way, should always be looked for in doubtful cases.

The fatality in this epidemic thus far is fortunately low. Early lumbar puncture is a useful procedure, and the same holds true of the administration of the salicylates and hexamethylenamine during the entire course of the disease. There is at present no positive evidence of the value of convalescent serum, either as a preventive or as a curative agent. Where cerebral symptoms prevail, warm baths are beneficial.

Of course, every suspicious case of the disease should be promptly isolated and the patient should be given the benefit of absolute rest to body and mind.

HERMAN B. SHEFFIELD, M.D.
127 WEST EIGHTY-SEVENTH STREET, NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, August 24, 1921.

The Health of London.—The annual report of Dr. W. H. Hamer, county medical officer of health of the County of London, on the health of that city, has just been issued. Some of the facts set forth therein are both interesting and important. The birth rate rose from 18.2 to 26.4 per 1,000. The death rate fell to 12.6, the lowest ever recorded. The infant mortality was 76, compared with England and Wales as a whole, and 85 for New York, the only other city of the world approaching in population to that of London. While these are the main outstanding facts many of the details of the report and some of the remarks of Dr. Hamer are highly interesting to those concerned with health problems in all parts of the world. Especially

should they attract the attention of the health authorities and medical profession of New York, which as said before, is the only other great aggregate of population which can be compared with London. A deduction drawn from the phenomenal general and infantile death rates mentioned in the report, as Dr. Hamer truly said, relating as they do to so large a population as that of the county of London is that it must give pause to those who advocate, at any rate, on grounds of health alone "a return to the land," and cause hope to spring in the breast of even the most gloomy and pessimistic of the four and a half millions of human beings whose avocations compel them to work and live within a few miles of St. Paul's. A death rate of 12.6, if it were possible to maintain it at that level for a series of years, would entail an average duration of life of the four score years deemed some thousands of years ago to be attainable only "by reason of strength and far exceeding the expectation of life of the first life table of William Farr, the pioneer British health statistician and of all the later tables, too.

Some observations of Dr. Hamer on the influence of migration from the country on London's health statistics and on the tuberculosis rate especially, give one furiously to think. He guesses roughly that nearly a sixth of the phthisis mortality of London is a mortality of men and women, chiefly men who have come to London after early middle life. He states definitely that this conclusion is not based merely on a priori reasoning, but on much close observation of London life and statistical matter. What he has to say on this subject is really of intense interest and applies quite as nearly to New York as to the British metropolis. He points out that it is now agreed that London draws in, as it were, like a vortex, the enterprising and ambitious boys and girls from all parts of the country. But perhaps even more important from the phthisis point of view is the fact that the lure of London continues to be exerted in later years. At the higher ages there are, however, marked distinctions and differences, qua sex and quality. The female immigration apparently reaches its maximum at an earlier age than the male, and the male curve continues at a higher level after the female curve has noticeably declined. Moreover, as the age of the immigrants is increased their quality becomes poorer, and this is particularly the case with the males. Young single men and single women coming to London are, as a rule, enterprising and ambitious. After a time the young men fetch up their sweethearts from the country and start housekeeping in London, and a considerable number of young married people, perhaps, with young families, come, too. There is a noteworthy falling off in immigration of women after 30 or 35, few country women come to London to stay there after 40, and very few after 50 years.

The essential importance of good nutrition in the upbringing of a healthy race is well brought out in the report. It is stated that during the war years there was a notable improvement in the general physical condition of the children as shown by the state of their nutrition. In 1919, however, it was remarked that there was a perceptible deterioration of their nutritional state, and that this was especially marked in the case of children entering upon school life, in whom it might be expected that the earliest reaction to adverse circumstances would be seen. Unfortunately, this deterioration has continued, and is now shown in boys and girls of all ages, but especially in the case of the eight-year-old group, in which the greatest amount of undernourishment is apt to be found. Although the deterioration is not as yet alarming, it is significant, and reflects the effects of combined high prices and unemployment.

Stammering appears to be a somewhat common affection among London children. The total number of notifications for this disability during 1920 was 914,682 boys and 232 girls. There were found to be two distinct sets of cases. In the first the stammering came on together with the development of speech; these cases were the more difficult to cure. In the second, the stammering came on later after a period during which the child spoke normally. Frights of various kinds were frequent causes, and among these air raids during the war played a part. Night terrors and nightmare were associated with many of these. The majority of children were found at the outset to possess very poor chest development with marked rigidity and spasmodic breathing. Part of the training was accordingly directed toward the improvement of the condition of the chest, particularly with the object of inducing relaxation. The reports for the whole of the year 1920 show that 225 children were treated, 106 were cured, 61 left before cure or were withdrawn for various reasons, and 108 were in attendance at the end of the year. It is instructive to note for the edification of those who believe that left handedness usually accompanies stammering, that this condition was found in only thirteen cases.

Meeting of the British Association.—The British Association for the advancement of science will meet in Edinburgh from September 7 to September 14, inclusive. Sir Edward Thorpe will be the president in succession to Professor W. A. Herdman.

The Use and Abuse of X-rays.—The lay papers here a few weeks ago "boomed" a new *x*-ray apparatus as a probable cure for internal cancer. Indeed, some of these journals went even further than this. The apparatus in question is known as the Wintz apparatus from the name of the Bavarian doctor, who has been employing it. It is not new in principle nor are the claims advanced for it by any means admitted in Germany. British radiologists feel very strongly on the matter; in fact, so impressed are they that unjustifiable and extravagant assertions have been made of its capabilities that an official statement is to be publicly brought out by the medical society which comprises the leading British practitioners of *x*-ray methods.

History of Deaf Mute Instruction.—The priority in this advance is usually given to Cardan with Fabricius ab Aquapendente as the practical successor. Recently Spain has asserted her claim as the rightful pioneer through the names of Pedro Ponce, a Benedictine, who was the original instructor (1500-1584), and Bonet, who published the first book on the subject in 1620.—*La Pediatria.*

2. End Results in Cancer Cases. Cancer of the Breast. Robert B. Greenough and Channing C. Simmons.
3. Myxedema Following Treatment of Graves' Disease with Roentgen Ray. Malcolm Seymour.

1. Extra Pleural Thoracotomy for Advanced Unilateral Pulmonary Tuberculosis. Report of a Case.—Wyman Whittemore and G. Lawrence Chaffin state that since the beginning of the use of pneumothorax in the treatment of pulmonary tuberculosis, there has been felt the need of a treatment for the 25 per cent. of the cases in which a satisfactory collapse of the lung cannot be effected, because of adhesions between the parietal and visceral pleuræ. It was for this group of cases that Bauer and Friedrich, in 1907, advanced the idea of an extra pleural thoracoplasty. The original operation of Friedrich has been greatly modified and a mortality rate of 25 per cent. has been reduced to one of comparative safety. Enough cases have been done in Europe with satisfactory results to urge that this operation be done more generally in the United States. The case reported is the only one treated by this method at the Massachusetts General Hospital. The patient was an Italian laborer, 34 years of age, who gave a history of eight years' duration. He was operated on August 3, 1920, by the method of Paulsen and Sangman, under regional and mass infiltration anesthesia, following preoperative medication with morphine sulphate. Subperiosteal resection of sections of the upper eleven ribs, beginning at the eleventh and working upward, was done, the ribs being sectioned posteriorly as near the transverse processes as possible, but it was not thought important to carry the anterior section too near the sternum. The sections of ribs removed measured from 2 to 11½ cm. The parietal pleura was freed forward and backward, from the chest wall, care being taken not to open the pleural cavity. After completing the operation a thick gauze dressing was held in position by adhesive and an especially made chest belt applied at once to compress the right lung. Following this the patient made rapid improvement under sanatorium treatment, and gained twenty pounds. After leaving the sanatorium he began to lose weight, but under hygienic home treatment was again improving rapidly.

2. End Results in Cancer Cases. Cancer of the Breast.—Robert B. Greenough and Channing C. Simmons urge the need of some uniform standard for reporting end results of operations for cancer in order that comparison of the work of different clinics may be possible, and accurate mass statistics obtained. In a recent paper on cancer of the breast an arbitrary standard was adopted, and that standard has been maintained in the present communication. It is as follows: (1) A definite period of time has been elected, ending at least three years prior to the report, and all the cases entered in the hospital records under the given diagnosis have been investigated. (2) No case has been accepted as cancer without proof by pathological examination, or subsequent recurrence, or autopsy. (3) Cases which have survived at last report, only a portion of the necessary three year period, are eliminated as inconclusive. (4) Cases not traced at all after discharge from the hospital, and not appearing in the mortality statistics of their place of residence, are eliminated as inconclusive. (5) All cases fulfilling the above requirements are published and counted in the statistics with such subdivision into radical and palliative operations as may seem expedient. A scheme for the reporting of end results is presented and also a study of 103 cases of primary cancer of the breast admitted to the Massachusetts General Hospital from August 1, 1911 to April 1, 1914. Of these 95 are available for the study of end results, which are compared with those of a series reported by the writers in 1907. In the later series the time limit has been extended for three to five years and in spite of this fact the percentage of "cures" for all operations has been raised from 19 to 27 per cent., and the percentage of "cures" for radical operation from 31 to 32 per cent. Details in regard to errors in diagnosis, operative complications, date and site of recurrences, variety of cancer, and involvement of axillary glands are given.

8. Standardization of the Wassermann Reaction.—Dr. John A. Kolmer describes his efforts to build up a new standard complement fixation test for syphilis. He does not call it a standardized test, however, because only future experience can tell whether it deserves that designation, but it is intended to meet the requirements of a standardized technic in the following ways: A. *Meeting the requirement of sensitiveness* by: (1) using a highly sensitive antigen; (2) using relatively large amounts of antigen; (3) using relatively large amounts of serum and spinal fluid; (4) heating serums for only fifteen minutes at 55° C.; (5) using a mixture of guinea-pig serum complements prepared in a manner tending to increase sensitiveness to fixation; (6) mixing serum and antigen for a brief period before the addition of complement; (7) using a primary incubation of from fifteen to eighteen hours at from 6° to 8° C.; (8) by close adjustment of the hemolytic system adjusted to cold primary incubation; (9) by using an antisheep or antiox hemolytic system; the test may be conducted with an antihuman system that is not as delicate as with an antisheep system; (10) by reading the reactions three hours after the conclusion of the secondary incubation. B. *Meeting the requirement of practical specificity* by: (1) adjustment of the hemolytic system to cold primary incubation; (2) adjustment of the dose of antigen to cold primary incubation, and (3) using numerous controls. C. *Meeting the requirements of technical accuracy and uniformity in results* by: (1) adoption of the principle that pipetting relatively large amounts of fluid (from 0.2 to 1.0 c.c.) tends to greater accuracy than measuring smaller amounts; (2) using a total volume of 3 c.c. with sufficient corpuscles and test tubes of suitable size to yield clear, sharp, and easily read reactions; (3) using a reading scale furnishing hemoglobin in solution and nonhemolyzed corpuscles in proper portions. D. *Meeting the requirements of a quantitative reaction.* This has been accomplished by employing a series of dilutions or doses of serum or spinal fluid. Extensive trials have shown that five doses (six tubes, including the serum control) are sufficient and a method

has been worked out whereby these may be prepared rapidly and accurately. The test also meets the requirements of economy and simplicity. The writer bespeaks the cooperation of serologists and asks them to give the new test a fair and unbiased trial for the purpose of gradually adopting a technic which the majority of serologists can subscribe to as being worthy of adoption as a standard complement fixation test for syphilis.

10. Experimental Inoculations in Scarlet Fever.—George F. Dick and Gladys Henry Dick have conducted inoculation experiments with whole blood of early scarlatina patients and with filtered throat mucus. In all, thirty volunteers were inoculated with eighteen strains of hemolytic streptococci, and then observed for sore throat, fever, and rash on the skin or palate. All were negative as to rash on the skin or palate. Seven developed sore throat associated with fever and leucocytosis without rash. Twenty-three were entirely negative. Nine inoculation experiments were done with a living pure culture of a pleomorphic organism similar to those previously found in cultures of throat, blood, and urine in early cases of uncomplicated scarlet fever. Attempts to prepare a satisfactory antigen of this organism for complement fixation tests were not successful. The strain used in these experiments was isolated from the throat mucus and the inoculation carried out by means of throat swabs. Two of the nine developed sore throat with fever, leucocytosis, and a rash on the palate, but did not show a skin rash. This organism evidently bore no etiologic relation to scarlet fever. In this series of inoculations no instance of typical scarlet fever was produced.

6. The Problem of the Head Louse. G. A. Auden.

4. Anesthesia with Nitrous Oxide and Oxygen Under Pressure.—H. H. Dale and Leonard Hill have carried out experiments on cats which showed that they cannot be deeply anesthetized by nitrous oxide until asphyxiation is partly induced. They then tried the same mixture, viz., eight parts of nitrous oxide to one part of oxygen, in the pressure chamber at the Lister Institute. The method of administration was absolutely the same except that the air pressure was raised to about 1½ atmospheres. The effect of the extra half atmosphere of pressure was to raise the partial pressure of nitrous oxide notably, and, at the same time, make that of oxygen much nearer to that in the air of the plains. In this way full, deep anesthesia without any deficiency of oxygenation was obtained. The writers believe that in an operating room built as a pressure chamber it should be a very simple thing to secure sufficiently deep anesthesia in man, using nitrous oxide and oxygen, four, five, or six parts to one, with safety and with freedom from symptoms of after poisoning and shock. An air compressor would be required to keep up the pressure at the extra half atmosphere, or less, and to ventilate the chamber, and an air lock would be needed to permit people to pass freely in and out. With such an apparatus it would be possible to overcome the present drawbacks to nitrous oxide oxygen anesthesia. It is hoped that it will soon be possible to bring the method to practical trial.

5. Nausea and Vomiting in Pregnancy.—Victor John Harding recalls that a little over two years ago he put forward the theory that the nausea and vomiting of early pregnancy is due to a deficiency in the maternal liver; that secondary factors are intestinal intoxication and neurosis; that as the condition progresses starvation and possibly dehydration intensify the symptoms to a degree known as pernicious vomiting, and that correct therapy consisted in the recognition of these factors and bringing them under proper control. In the present communication he extends and amplifies the contention of the previous report and states that nearly two hundred cases have been treated by carbohydrate feeding with but few failures, and those due to deliberate and continued breaking of dietetic regulations, or to the fact that the patients came in such advanced stage of pernicious vomiting that it was doubtful if any treatment would have been of avail. The treatment consisted in the use of glucose to restore and maintain the glycogen content of the maternal liver; a high carbohydrate diet, from which fats might be excluded for a considerable time; rest and isolation, with a cautious use of sedatives to control the neurosis, and the use of water, by mouth, if possible, if not by enemata, or by glucose solution administered intravenously, to combat any dehydration.

3. Typhoid Fever in an Infant Complicated with Suppurative Arthritis. E. N. Russell.

1. Adolescent Tetany and Its Relation to Guanidin.—F. J. Nattrass and J. S. Sharpe assert that from the observations of a number of investigators the conclusion seems inevitable that the symptoms of tetania parathyreopriva and of idiopathic tetany of children are both due to some error in the metabolism of guanidin in the body. Findlay and Sharpe, in 1920, recorded a case of adult tetany in which the excretion of guanidin in the urine and feces was markedly above normal. They now record another case of the same kind in which the excretion of guanidin in the urine and feces was estimated. The patient was a girl of fifteen years, who gave a history of painful spasms of the hands for about a year before coming under observation. The attack occurred apparently from no cause. An attack in one hand would be induced by pressure on the corresponding nerve trunks in the upper arm (Trousseau's sign), and a very severe attack in the right hand followed shortly after galvanic testing of the right ulnar nerve. There was also a history of tetany in a brother and a sister of the patient. The patient was placed on a creatine-free diet and the excretion of guanidin estimated by the pierate method, and found to be in excess of normal. The patient showed a slight, uniform enlargement of the thyroid gland, no greater than that often seen in girls at puberty, and no signs of hyperthyroidism. She was treated over a long period with parathyroid and thyroid tablets with no appreciable effect. Neither has the administration of salol by mouth appeared to diminish the attacks.

2. The Sachs-Georgi Precipitation Test for Syphilis.—T. Taniguchi and N. Yoshinare have compared the results of the Sachs-Georgi and Wassermann tests in a series of 1,575 serums, comprising cases submitted to the laboratory from the wards of a general hospital, as well as the venereal diseases center. The results of the two tests were parallel in 90 per cent. of the serums examined. There were discrepancies in 157, or 10 per cent., of the cases. In 23 of these there was a positive Wassermann but a negative or doubtful Sachs-Georgi reaction; in 77 there was a negative or doubtful Wassermann but a positive Sachs-Georgi. When cases of syphilis which had undergone specific treatment are grouped by themselves the proportion of positive results with the Sachs-Georgi test is greater than with the Wassermann reaction. Attention is directed to the following practical points in performing the test: (1) Heated serum should be used; unheated serum from positive cases may fail to cause precipitation in any concentrations. (2) The concentrations of serum recommended should not be exceeded, since heated normal serums in large amounts —for example, 0.2 to 0.3 c.c.—may cause precipitation. No positive case has been met with in which the usual amounts of heated serum employed failed to show pre-

cipitate, but the reaction may be more marked with 0.05 c.c. than with 0.1 c.c. (3) The mixture must be kept at 37° C., as a precipitate may form with non-syphilitic serums at lower temperatures. Sometimes, however, it is an advantage in the case of weak reactions to record the results after the tubes have stood for thirty minutes further at room temperature, but the behavior of the negative control must be carefully scrutinized. (4) The results should be controlled by including in each series of tests known negative, weak, and strong positive serums, just as in the case of the Wassermann reactions.

1. Ruptured Spleen. Spontaneous and Subcutaneous.—John F. Connors reviews the history of splenectomy, quotes the history of twelve cases of spontaneous rupture of the spleen reported in the literature, and reports three cases of splenectomy in children in whom rupture of the spleen was caused by the wheels of a wagon passing over the abdomen. He also records a case of spontaneous rupture of the spleen in which there was no history of malaria, typhoid, or typhus fever. He brings out the point that study of the histories of rupture of the spleen show that the majority of cases have occurred at or near the point of maximum enlargement a few hours after taking food. It appears also that the loss of the spleen has made no difference in the physical welfare of these patients. The most important changes in the cases of splenectomy for trauma have occurred in the blood, and are more marked than in cases in which the spleen has been removed for disease. The most important changes are an increase in the leucocytes, characterized by a relative increase in the mononuclears. The erythrocytes decrease in number but gradually increase with the increase in the percentage of hemoglobin. It has been observed that a moderate æsinophilia occurs and may persist for a considerable length of time. In the writer's cases the blood picture at the last examination revealed but a slight deviation from the normal. Faltin and Stubenrauch found at the time of second laparotomies, one and six years, respectively, after splenectomy, that the peritoneum of these patients was covered with numerous nodules, showing microscopically the characteristics of splenic tissue. Similar observations were made by Guerrini on a dog after splenectomy. Such findings suggest that small accessory spleens occasionally undergo hypertrophy and functionate in place of the missing main organ. It is desirable that such hyperplastic accessory spleens be looked for in the future, in autopsies performed a considerable time after splenectomy. The author does not agree with Auveay and Vauverts, who advise resection of the costal border in performing splenectomy; he believes there is sufficient room with the abdominal incision. Resection of the costal border necessitates a longer operation, and splenectomy should be done as quickly as possible. A study of the literature shows that results in splenectomy are steadily improving, due largely to the use of direct blood transfusion which is being resorted to more frequently.

6. Fracture of the Skull in Children.—Dr. John J. Moorhead and Walter Weller summarize their findings based on an analysis of one hundred cases of fracture of the skull in children, treated by four visiting surgeons or their associates or assistants at the Harlem Hospital, as follows: (1) A combination of vault and basal injury can be expected in a very large percentage of cases in which the injury has been severe, and when the violence has not been direct and localized in character; in the latter vault injury is more usual. (2) The mortality in this series was 26 per cent., in which 5 per cent. followed vault fracture, and 10 per cent. basal, and 11 per cent. combined vault and basal injury; in other words, involvement of the base gave a mortality four times that of the vault. If associated injuries are excluded the mortality in this series is 17 per cent. (3) Early death, within forty-eight hours, was due to the head injury or associated injury; thereafter infection in the form of meningitis, often pneumococcic, was the chief factor. Sixteen of these cases died within twenty-four hours, four within forty-eight hours; this means that over three-fourths of the fatalities occurred within the first two days. (4) Fifty-one per cent. of the quoted cases involved the vault, with a mortality of 5 per cent.; 17 per cent. involved the base and vault, with a mortality of 11 per cent. (5) By comparison with adults, children have a 25 per cent. better chance for life with an equal grade of skull injury. (6) The number of cases requiring operation is relatively small; in this group 12 per cent. were operated upon.

7. The Value of Dakin's Solution in the Treatment of Thoracic Empyema.—Abraham O. Wilensky concludes from his experience that in actual practice the use of the Carrel-Dakin method in the treatment of empyema wounds has but a limited use. The method is not feasible in the presence of any sort of reinfection (insufficient drainage of any kind, osteomyelitis of the rib, etc.)), in the presence of any communication with the bronchial tree, in empyemata other than the simple pyogenic varieties, in empyemata whose contour is other than the very simplest, or in empyemata the mechanical conditions of which are not conducive to a reasonably prompt healing (collapsed lungs). The method is very useful in the relatively small minority of small encapsulated empyemata and which do not suffer any of the drawbacks or complications previously indicated. Under even these ideal conditions the method has not, in the writer's experience, shortened the length of time necessary for the complete cicitrization of the wound. This is probably due to the constant care necessary in carrying out the details of the dressing, and even in the best of hands breaks of technic are constantly occurring. As soon as these occur the even progress of healing is interfered with and time is lost. Experience has shown that it is wisest not to suture secondarily the outer wound because of the numerous recurrences, but to allow the outer wound to close spontaneously after the cavity is supposedly sterile under a dry or other innocuous dressing. One cannot but gain the impression that in the cases in which the use of Dr. Dakin's solution is satisfactory, a healing similar in all respects would be obtained without the use of this antiseptic solution if the same meticulous care were exercised in the postoperative management as is necessary according to the precepts of this method.

Endocrinology.

1. The Parathyroid Glands. Walter M. Boothby.
2. Epilepsy Suggestive of Endocrine Relationship. Henry J. Van den Berg.
3. Does the Administration of the Anterior Lobe of the Hypophysis to the Tadpole Produce an Effect Similar to That Obtained from Thyroid Feeding? Philip E. Smith and Garnet Cheney.
4. The Internal Secretion of the Spleen. Nathan B. Eddy.

1. The Parathyroid Glands.—Walter M. Boothby reviews the literature, and summarizes our knowledge regarding the functions of the parathyroid glands as follows: (1) In many species of animals the removal of all parathyroid tissue causes death from tetany, within a few days in most instances; the herbivora are less liable to tetany than the carnivora; age appears to have a definite influence on its frequency and severity, as do pregnancy and lactation. There is some evidence of late trophic changes in those animals that survive parathyroidectomy and have few or no tetanic symptoms. (2) The preservation of very small amounts of parathyroid tissue prevents or renders tetany less intense. (3) From the evidence at hand, the function of the parathyroids appears to be distinct and separate

from that of the thyroid; their only relationship appears to be anatomic and not functional; the parathyroids are not embryonic thyroid tissue. (4) There is evidence that their function is in some way concerned with calcium or guanidin metabolism or both; they may play some part in the regulation or maintenance of the acid base equilibrium in the body. (5) The experimental evidence pointing to the parathyroids as the primary cause of idiopathic tetany, unassociated with operative procedures on the thyroid, is very limited. (6) The only definite clinical entity which has yet been proved experimentally to be of parathyroid origin is the tetany occasionally seen after operations on the thyroid. In these conditions calcium in large doses usually ameliorates the symptoms. The reports as to the benefit obtained by parathyroid transplantation or feeding are not convincing.

4. The Internal Secretion of the Spleen.—Nathan B. Eddy reports experimental work on rabbits which lends support to the hypothesis that the spleen produces an internal secretion. This evidence consists in (1) the changes in the erythrocytes after splenectomy, (2) the modification of the blood picture in hyperplasia of the spleen, ameliorated in some cases at least by splenectomy, and (3) the specific effect on the red blood corpuscles of injection of splenic extract. He says that we know nothing of the chemical nature of the supposed splenic hormone and it is difficult to formulate a consistent theory of its possible mode of action, but suggests that the chief function of the spleen is the removal from the circulation of the disintegrated erythrocytes; that the splenic cells elaborate this material, producing thereby an internal secretion which was a component of the erythrocyte, either stroma or pigment portion; that this internal secretion reduces the resistance of all red blood corpuscles, the effect amounting to actual destruction of the older cells; and, finally, that this internal secretion, possibly after modification by the liver, stimulates the erythrogenic function of the bone marrow and is used up in the manufacture of new corpuscles.

6. Tribute to Dr. F. L. Hoffman. Rudolph Matas.

2. Recent Work on Inorganic Constituents of the Blood.—W. Denis calls attention to a study by Denis and Minot in 1920, in which it was found that 65 per cent. of a considerable number of blood samples of nephritic and cardiorenal cases showed unmistakable evidence of phosphate retention. It was further noted that fatal cases showed a rapid and progressive increase in plasma phosphate, increases of more than ten times the maximum normal value being not uncommon; on the other hand, the non-fatal cases, even though the patient was seriously ill, presented a relatively slight increase. It has been found that there is no definite relation between the level of inorganic phosphate, non-protein nitrogen, and of the alkaline reserve. In several cases in which the alkaline reserve was extremely low, and the level of inorganic phosphate high, intravenous injection of sodium bicarbonate given in amounts sufficient to produce a distinct alkalosis was absolutely without effect on the level of the plasma phosphate. The results so far obtained would suggest the possible prognostic importance of the determination of inorganic phosphates in the plasma of persons suffering from nephritis or allied disorders. So far no condition has been noted in which abnormally large amounts of calcium are found. It has been demonstrated, however, that in parathyroid tetany, pneumonia, acute rachitis and uremia, there is a marked decrease in the calcium content of the plasma. That the tetany of parathyroidectomized animals or of rachitic children is due to a decreased blood calcium alone is questionable. It would seem rather that such abnormal manifestations might result from a disturbance of the equilibrium between calcium and other inorganic electrolytes of the blood.

3. Hemorrhage into the Upper Digestive Tract.—Sidney K. Simon reports three cases occurring within a comparatively short period, in which there was massive hemorrhage into the digestive tract apparently as a result in each instance of a diseased state of the arterial system with especial localization in the vessels of the stomach and duodenum. He says that notwithstanding the fact that rupture of a diseased vessel wall with ensuing massive hemorrhage is an event of common occurrence in other organs, it would seem from a careful survey of the literature that a similar accident along the gastrointestinal tract is one rarely, if ever, encountered. It should not be overlooked that simple arterial rupture is possible along the gastrointestinal tract, without previous ulceration, simulating a pathological picture not infrequently presented in other organs; notably the brain. One might even consider an apoplexy of this type, within the free lumen of the digestive tract, as a life-saving effort, sparing the more serious consequences which would await a vascular accident of similar nature in more vital organs.

The Rectal Magnesium Treatment of Tetanus.—Hotz reports a case of lockjaw from a pediatric clinic, the patient being 10 months old, and the disease idiopathic or at least there could be found no sign of traumatism. The child was in the midst of an attack of chickenpox and the bacilli of tetanus are believed to have entered the organism through one of the pocks. Treatment comprised chloral per rectum with magnesium sulphate subcutaneously. This treatment was maintained for 16 days. Serum was given several times, but evidently it was not intended to be the chief reliance. At the end of the 16-day period the child was so covered with needle punctures that the magnesium was given by enema—10 c.c of the 20 per cent. solution. The improvement was startling. For the next 6 days only enemas were given and the results were all that could have been obtained from subcutaneous exhibition. If further experience be as favorable the change will doubtless be upheld for routine work because the subcutaneous injection of magnesium sulphate is apt to precipitate convulsions of tetanus, and, as has also been noted, of tetany as well when used in spasmophilia. The author also suspects that the fever seen in this patient after he had been on the mend was also due to the subcutaneous use of the drug. The author writes at considerable length concerning the action of this salt, but, with the German's facility for purloining ideas, nowhere mentions the name of the late Dr. Meltzer, who originated its use in tetanus and who wrote numerous articles on the subject in which he defended the value of his discovery against its critics.

The Extinction Phenomenon in Scarlatina.—Reymond writes this paper from Professor Feer's pediatric clinic. The phenomenon in question has to do chiefly with the differential diagnosis of scarlatina from measles and various rashes. It is based on the discovery in 1918 by Schultz and Charlton of a certain property of normal human blood serum when injected into the skin of a scarlet fever case. The result is the disappearance at the end of seven or eight hours of an area of the rash about the puncture. The injection is made directly into the exanthem and but a few square centimeters of the latter pale out, but this result is not seen in any other rash or skin disease. This extinction may be effected by any human serum, even that of a subject who has never had the fever. The only known exception is the serum from a patient in the early stage of the disease. The author has tested 97 eruptive patients, of whom 84 were scarlatinous. The total number of injections in this series was 145. In the

scarlatinous series there were 25 negative results. By eliminating some of these because too late in the evolution of the disease or for other plausible reason the per cent. of positives may be raised to 82. Of the surely negative there were a number in which the diagnosis may have been open to some doubt. The results of other authors, however, show that the test cannot be regarded as infallible. The author was unable to produce extinction of the rash in any other malady, although some observers claim to have seen the phenomenon in measles and toxic erythema. No animal serum has ever produced a positive result to date. The test should be made in the first three days of the rash and the power of the serum persists for about three weeks when taken from a scarlatinous subject.

Superinfection in Tuberculosis.—Lavergne discusses this subject with especial reference to prophylaxis. Its importance appears in the fact that some systematic writers ignore it entirely. The author, however, takes the existence of superinfection for granted and hence it is necessary to ascertain the exact significance which he gives to the term. In the only case narrated the subject was a boy about 3½ years old, born at term and of normal weight. The father was healthy, but the mother had had attacks of dry pleurisy. She was unable to nurse the infant. At the age of three months the latter was vomiting its bottled food, but the condition yielded to the proper treatment. At the age of 14 months there were fever and emaciation, and not only the child but the mother presented clinical evidence of tuberculosis. The mother showed an abundance of Koch's bacilli in the sputum, while the child gave a positive cutireaction. Apparently the latter had been contaminated, presumably by its mother, at the age of 10 to 11 months; for the mother had begun to ail about that time, and the actual symptoms in the child went back two months, leaving several weeks for an incubation period. It seemed hardly possible to separate mother and child, yet the danger of massive superinfection from the mother was great. The patients had the benefit of a sojourn in the country and the child was operated on for adenoids with benefit. At one period it seemed threatened with meningitis, but improved rapidly on mercurials. The *x*-ray showed tracheobronchial adenopathy, with the physical signs of pulmonary lesions. At the present moment the child is in its fourth year and in fairly good condition despite the fact that it had never left its mother's side. The mother had never been free from bacilli in the sputum and the author assumes that she had constantly superinfected the child, although the latter not only survives her, but may even have acquired a certain degree of immunity.

July 23, 1921, xxix, 59.

Nature of Essential Epilepsy.—Pagniez contributes a synthetic review of this subject. Fleury, writing of essential epilepsy only, sees two components, one an injury, so to say, of the nervous system and the other an intoxication, perhaps alimentary. In certain cases the injury is evident, in others only presumptive; and this is also true of the toxic factor. But on the whole pathological anatomy is reticent about the nature of these lesions, the possibly constant presence of which has been made more probable by many war cases. Extensive statistics of cases following cranial injuries are now available. Convulsions which supervene at an early period following injuries are not included. Jacksonian cases occur as a rule earlier than generalized cases. Hence the relatively late supervention of the latter has been brought into association with the formation of the scar. It seems plausible to associate this process with the development of general convulsions. This is in accord with observations of cases of infectious encephalitis which have been followed by epilepsy. In a case quoted, an arteritis of the brain following paratyphoid led to a focus of softening and later there developed in succession petit and grand mal epilepsy. The interval corresponded with that of cicitrization of the softened area. The old dispute as to whether the brain is anemic or congested during a major epileptic paroxysm has been revived by the experience of Leriche, who in two cases saw the traumatic area in the cortex, which had been responsible for the epilepsy, pale out during the seizure; as a result apparently of active vascular contraction. Doyen is said to have had the same experience, while Knies saw the fundus oculi blanch under the same circumstances. The hypertension seen in the trephined by Ebaugh and Stevenson, which persisted through the conclusive stage and later, is evidently not a constant phenomenon, for the very converse has been noted in other trephined subjects. Passing to the toxic factor, the author quotes the work of Plantier on digestive intoxication as an important document to the subject. This phenomenon can only occur at intervals and something concerned therein has evidently a cumulative property. When a certain degree of preparation has occurred something is evidently set free in the body which produces the vasomotor spasm responsible for the seizure. But why does not this toxic body manifest its presence by casual symptoms? The author replies that this is exactly what does happen. Certain changes in the blood and cerebrospinal fluid have been noted, although they are not constant. The possibility that a digestive anaphylaxis causes the epileptic paroxysm has been much agitated, but the evidence is not convincing. In anaphylactic shock the blood pressure is lowered, while in an epileptic paroxysm it is elevated. Again in petit mal the analogy is very slight or absent. But to go to the other extreme and state that there is absolutely nothing in common between epilepsy and anaphylaxis is much too reactionary, for the two have much in common—sudden onset, a vascular component, connection with digestive disturbance, etc. Moreover, many known anaphylactic phenomena, as urticaria, asthma, and migraine, have some connection with epilepsy, occurring as "equivalents" (?) or in epileptic families. In rare cases epilepsy itself has seemed to depend on special ingesta, as sweets. Recently a number of reports of the application of proteintherapy in epilepsy have been published. The original is doubtless the crotalin or snake venom treatment, now long known, but quite recently peptones, milk, tuberculin, horse-serum, autohemotherapy, etc., have been tested in different clinics with varying results, some of them, however, fairly good, according to the reports.

La Medicina Ibera.

The Mortality in Madrid from Cancer.—Lasbennes quotes figures which cover twenty years, beginning 1901. The steady increase in the annual number of deaths might be set down as due to the growth of the city, but the percentage per thousand inhabitants also shows a steady increase. In fact, this percentage, which was 0.8 per 1,000 in 1901, was last year 1.16. The incidence in males has considerably more than doubled in twenty years, while that in women is greater by 3 to 2. The principal element of increase is apparently in the direction of cancer of the stomach. In 1901 this class was represented by 108 cases all told, while in 1920 the corresponding figure was 269. On the other hand the increased incidence of cancer of the uterus and breast is not so great that it could not be explained by increase in population. The total loss from cancer, etc., for the twenty-year period was 11,601, and the annual loss therefore under 600. The cancer death rate of Madrid is therefore about the same as that of Greater New York, which, with as much as tenfold the population of the Spanish metropolis, has a cancer death loss of from 5,000 to 6,000 annually. The author makes but few comments; his statement that social status and occupation cut no figure doubtless means no more than that there is no exempt class. He finds a constant sex ratio of three women to two men, which exactly inverts the tuberculosis ratio of two women to three men. He also adds that cancer of the stomach is on the increase in women as well as men.

Book Reviews.

COMMON INFECTIONS OF THE KIDNEYS WITH THE COLON BACILLUS AND ALLIED BACTERIA. Based on a Course of Lectures Delivered at the London Hospital. By FRANK KIDD, M.B., B.C. (CANTAB.), F.R.C.S.ENG., Surgeon to London Hospital; Surgeon-in-Charge of Genito-Urinary Department, London Hospital; Member of the International Society of Urology; Membre de l'Association Française d'Urologie. With an Additional Lecture on the BACTERIOLOGY OF THE URINE, by Dr. PHILIP PANTON, Clinical Pathologist, London Hospital. New York: Oxford University Press, American Branch, 1920.

IT always seems like giving away the kernel of a joke or the answer to a riddle when the content and summary of a book are offered in review. But this book is such a delight for the manner in which the subject matter is handled, the language in which valuable material is given to the reader, and for the strength and virility expressed in every page.

Says the author, "The time has come to try to make medicine more simple by elaborating wider principles that can subsume a large number of phenomena. If the student and practitioner are adequately trained by explaining to them the larger principles, they can apply these for themselves to their cases in practice and obtain a wider interest and better results." Again, there is a temptation to applaud the writer when he says, "It has been too much the fashion to make medical books and papers an elaborate summary of the literature. . . . Men are afraid to use their own eyes and to draw their own conclusions from their own observed cases. They have been too frightened of the literature, much of it mere hack work and based on insufficient observation. . . . My method is to study certain cases over a period of years with the most developed weapons of my specialty. . . . and draw the deductions that seem warranted by the facts." "The present work endeavors to give a picture of common infections of the kidney, bladder, prostate, and testicle with the colon bacillus and allied organisms. Such infections are of everyday occurrence in practice, yet the practitioner has so far had no certain guide to lead him in dealing with them." And the author carries out his intention so well that any reader interested at all in this subject would wish that even more detailed observations, conclusions and treatments had been included. The work is sufficiently illustrated, and on the whole is a unique and much-to-be-prized book on this specialty.

THE LOGIC OF THE UNCONSCIOUS MIND. By M. K. BRADY. New York: Oxford University Press, American Branch, 1920.

"THIS book purports to be a sketch, not a finished thesis, for which the author would be ill qualified." "Logic has seemed to many people in modern times a dry and abstract study only remotely connected with real life, but this, we venture to think, is because the science has to be re-formed, for we have outgrown the logic of our forefathers, just as we have outgrown their chemistry. . . . The student of logic today is called upon to give the subject a fresh start, and this he is enabled to do by the discoveries of psychoanalysts concerning the unconscious mind. Equipped with a new understanding of human motives, he has to look at people's reasoning, his own and others', and see what connecting principles may be observed, what general laws are actually in operation."

Thus the author speaks, and her purpose is carried out in this book in a sincere manner with a style that certainly should appeal to those who love to delve into the unseen causes for both clear, keen, and stupid motives for the activation of the human race. The simplicity employed in the presentation of her reasoning and in the statement of her facts is most refreshing after the deluge of almost unintelligible reading matter that has been launched on the public this past year with relation to psychoanalysis and allied subjects.

Her encouraging viewpoint is offered in these words: "The view of life which thus presents itself is full of hope, for it is seen that the dearest wishes of the heart whether past or present, primitive or advanced, are those belonging to the dawn. Two things delay their consummation, ignorance and ill-will. The battle is not over, but till the present, enlightenment and goodwill win the day." "It may be that a vision of the ultimate triumph of love brings little consolation to the victims of present hatred—a hatred destined to blight the lives not only of themselves, but of their children's children. Neither can all men feel the joy of worship, the passionate and enduring triumph of him who recognizes the supremacy of love, its place in the world of thought and things."

Comparatively few women have attempted to write on such a subject, so, again, this work is interesting because it gives the avenue of attack and of thinking on such an apparently speculative matter from the angle of a trained feminine mind. Perhaps, later, when more women have the courage to stand the training, the contributions from the woman mind on the unconscious life from the feminine standpoint, will offer a wealth of true sentiment intertwining the cold facts, which will give a tremendous insight and impetus to life itself and the clearer living and understanding of it and what it means. The last word has not been said; in fact, the first frail efforts have barely been put across when it comes to the understanding of human nature. Certainly a keenly-trained, keenly-thinking woman mind has much to offer and a bigger field could not be desired for her efforts.

INJURIES OF THE PERIPHERAL NERVES. By HENRY S. SOUTTAR, F.R.C.S. Eng., Late Senior Surgeon, British Red Cross Hospital, Netley, and EDWARD W. TWINING, M.R.C.S., L.R.C.P. Lond. Medical officer in Charge of Physical Treatment Department, Pensions' Hospital, Netley. Price, $4.50. New York: William Wood & Company, 1920.

THIS volume contains but 30 illustrations and hence can hardly be said to have an atlas component. The 24 chapters include such subjects as changes in the nerve and outlying tissues, examination for sensation and motion, results of the various nerves, differential diagnosis, the phenomena of recovery, the period of preparation, general operative technique, nerve suture, nerve resection, difficult suture, operative technique of special nerves, physical treatment (4 chapters), prognosis, alterative methods, and painful lesions.

THE ORIGIN AND DEVELOPMENT OF THE NERVOUS SYSTEM FROM A PHYSIOLOGICAL VIEWPOINT. By CHARLES MANNING CHILD, Professor of Zoology, University of Chicago. Price $1.90. Chicago: University of Chicago Press, 1921.

THIS small volume comprises 14 chapters, the last being merely a general résumé. The others are The Problem of Pattern, The Axiate Pattern (3 chapters), The Organismic Pattern (2 chapters), Relations of Central Nervous System to Other Portions, Segmentation, Centralization and Cephalization, Problem of Neuron Pattern (2 chapters), Transmission and Conduction and the Reflex Arc. There are 70 illustrations and an extensive bibliography. The plan of the work comprises the discussion of pattern and its relation to gradients. Concerning the latter there has been nothing published since 1915. This discussion furnishes the groundwork of the book.

THE EXTRA PHARMACOPŒIA of Martindale and Westcott. Revised by W. HARRISON MARTINDALE, Ph.D., F.C.S., and W. WYNN WESTCOTT, M.B., Lond., D.P.H. Seventeenth Edition. Vol. II. London: H. K. Lewis & Co., 1921.

THE amount of information contained in the two volumes of "The Extra Pharmacopœia" is enormous, as those who have seen it pass through its successive editions, each one fuller than the preceding, well know. The book has become so well known, indeed, that to review it seems quite unnecessary. The first volume of this edition was noticed some time ago and now the second has appeared, completing the work. As before, this volume is concerned chiefly with tests of various kinds, analyses of milk, water, blood, urine, etc., bacteriology, and laboratory work in general. A long section on radium and other radioactive substances is especially noteworthy. This new edition, like those that have preceded it, is literally invaluable as a guide to therapeutics and as a work of reference on all matters pertaining to materia medica, pharmacology, and organic analyses.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-Sixth Annual Meeting, Held at Swampscott, Massachusetts, June 2, 3 and 4, 1921.

THE PRESIDENT, DR. WALTER WILLIAM CHIPMAN, MONTREAL, CANADA, IN THE CHAIR.

Basal Metabolism in Pregnancy and the Puerperium.—Dr. JOSEPH L. BAER of Chicago said that the increased basal metabolic rate in late pregnancy was due to the growing demands of the fetal organism and placenta. The incomplete or delayed return to normal was due to involution of the uterus and the onset of lactation. Twin pregnancy should show a rate above the average for single pregnancy when both twins were well developed. Thyroid enlargement might occur in pregnancy without increasing the basal metabolic rate above the averages obtained in this series. Differential diagnosis between uterine tumor and pregnancy would not be helped unless greater refinements in method showed increased rates much earlier than in this series. The *x*-ray could be called on as early as the fifth month and with reasonable certainty in the sixth month.

Vaginal Supracervical Hysterectomy with Interposition of the Cervical Stump for Cystocele and Procidentia Associated with Enlargement of the Uterus.—Dr. HIRAM N. VINEBERG of New York City stated that in over one-third of the cases of procidentia and cystocele the uterus was found too large to be adapted for interposition. Decreasing the size of the uterus by excising a portion of the anterior wall or fundus had been found unsatisfactory on account of the rarity of obtaining primary union of the thickened and diseased walls of the uterus and the consequent high morbidity and mortality. A much more advantageous procedure consisted in amputating the body of the uterus at the level of the internal os or higher up (if the patient was under 40 years of age) and interposing the cervical stump.

Certain Dietary Factors in the Causation of Sterility in Rats with Speeal Reference to the Histology.—Dr. EDWARD REYNOLDS and Dr. DONALD MACOMBER of Boston, Mass., stated provisionally that a moderate decrease in the percentage of the fat soluble vitamine, of the proteid, or of the calcium contained in an otherwise excellent diet produced a definite decrease in the fertility of individual rats. A slight decrease in the fertility of both partners would produce a sterile mating. The fertility of the mating might be stated as the product of the fertility of the individuals concerned. If the index so obtained fell below a given point the mating would be sterile, and this result held true whether the partners were of equal or of widely different fertility. These principles explained the fact that two individuals, which were sterile when mated together, might nevertheless reproduce freely when mated to new partners (of higher fertility). Dietary deficiencies produced a lowered fertility which varied in degree with different individuals though of the same percentage and in the same cage. Diminished fertility sometimes resulted in the appearance of abortion. Mere percentage deficiency in both proteids and calcium produced visible ill health and great fertility.

Radical Conservatism in the Surgical Treatment of Chronic Adnexal Disease.—Dr. FREDERIC C. HOLDEN of New York City said that it had been demonstrated that pyosalpinges might be incised and suspended without mortality or excessive morbidity. A young woman with chronic adnexal disease, when physically disabled, and not responding to several weeks' rest and treatment, should be offered a choice between radical operation with its surgical menopause and conservation with its possibility of reoperation. In the event of conservation of ovarian tissue being decided upon, the technique described in his paper might be of benefit.

The Disposition of the Uterus Following Salpingectomy Where It Is Desirable to Preserve Menstruation.—Dr. CAREY CULBERTSON of Chicago stated that ventral fixation of the uterus had objections which rendered it an undesirable procedure in association with removal of both tubes. Round ligament shortening was unsuitable where the tubes had been removed and should be reserved for the simpler uterine displacements where pregnancy was to follow. The reduction of the uterus in size by removal of its entire fundus was a ready method of disposing of the organ after salpingectomy where, particularly in young women, it was desirable to preserve menstruation. Defundation became a logical procedure not only in operating for the cure of infectious processes, but also for simple sterilization, for ectopic pregnancy, ovarian cystomata and like conditions. Its only contraindication from a technical point of view was that of procidentia uteri.

Pneumoperitoneum and Roentgenology as Aids to More Accurate Obstetric and Gynecologic Diagnosis.—Dr. REUBEN PETERSON of Ann Arbor, Mich., said that the pneumoperitoneal *x*-ray was a great aid to accurate obstetrical and gynecological diagnosis. In suitable cases and with the proper technique gas inflation was free from danger. The apparatus for gas inflation and pelvic roentgenography was simple and inexpensive and could be used in any obstetrical or gynecological examining room. The method should not be used in cases of acute pelvic inflammation or when disturbances of circulation might arise from sudden abdominal distention. Since carbon dioxide gas was absorbed within half an hour it was preferable to use oxygen for inflation since the latter gas might not be absorbed for days. Whenever possible, the transuterine should be chosen in preference to the transperitoneal route for the introduction of the gas because of the valuable information it furnished regarding the permeability of the Fallopian tube. Excessive quantities of gas caused great pain. Experience had shown that for the ordinary case 1,000 cubic centimeters of gas would cause only moderate discomfort and was sufficient for good roentgenograms. With the proper position (partial knee chest with tilted table) and the ray directed perpendicularly to the plate in the axis of the pelvis, the pelvic organs were clearly shown by roentgenography.

Concerning Torsion of the Uterine Adnexa Occurring Before Puberty, Together with a Consideration of Torsion of Normal Adnexa; Report of a Case and a Review of the Literature Since 1900.—Drs. RICHARD R. SMITH and WILLIAM J. BUTLER of Grand Rapids, Mich., said that torsion of ovarian tumors was an uncommon occurrence in childhood, as shown by the fact that only 26 cases, including their own, had been reported in the literature since 1900. About 50 per cent. occurred between the ages of 8 and 10. Sixty per cent. of them were dermoids. The tumors varied in size from that of an adult ovary to one reaching above the umbilicus. The symptoms were those of an abdominal crisis similar to that of the same accident in adult life, sudden abdominal pain, vomiting, a variable degree of prostration, tenderness, rigidity, distention, temperature, increased pulse rate, and the presence of an abdominal tumor. The diagnosis was usually difficult, probably due to rarity. Appendicitis was often the preoperative diagnosis. The causes were much the same as in adult life. Fourteen cases of claimed torsion of normal adnexa had been reported to date. Eight of 14 cases, more than half, occurred before the age of 20; 4 under 12, and presumably before puberty. The tube alone might be involved, the tube and ovary together, or the ovary might be essentially the offending organ. A large percentage occurred in close relation to the menstrual period. Three were reported during pregnancy. Some question still existed as to whether a normal tube could undergo torsion, but it seemed to be proven that a normal ovary might do so. Factors, such as the length of the mesentery, the size of the ovary, and the length of the tube, must be considered as well as the histological structure of the organ. Torsion of adnexa in hernial sacs (apart from strangulation) was relatively rare. It occurred only in congenital inguinal hernias and usually in the first year of life.

The Fads and Fancies of Obstetrics: A Comment on the Pseudoscientific Method of Modern Obstetrics.—Dr. RUDOLPH W. HOLMES of Chicago stated that in safe and conservative hands maternal and fetal mortalities had decreased in private practice. The maternal and fetal death rates in hospitals had not shown any appreciable decline in 100 years. The fact that the death rate among the emergency cases (*i.e.* those

sent in by medical attendants) was over 10 times that of regular applicants in the New York Lying-In Hospital was a reflection on the preliminary medical training of the profession. Scientific investigation of antenatal pathology which would promote a prophylactic therapy would lower infant mortalities more than would the present attempts to do so by routine operative termination of labor. A properly conducted prenatal clinic, combined with conservative conduct of labor was a more certain method for securing declining death rates than promiscuous intervention. Under normal conditions, spontaneous labor, aided by proper analgesia was the safest way for mother and child. Inordinately applied operative interferences increased the hazards of birth. The authorities who had fostered a peculiar method of routine interference in all parturient women, with their imitators, had retarded the advance in obstetric care, and were part contributors to the high American mortalities incident to childbirth. It was a lamentable thing that properly controlled midwives would have less mortality than those who practised a routine intervention. The proponents of operative cults had produced no evidence to show that their systems were more worthy, less risky, and promised a higher conservation of life than carefully watched spontaneous labor. There were no more reasons why all parturient women should be operatively delivered than that all people should be inflicted with routine enemata or catheterization. A medical fad should be discountenanced; precept and example founded on injudicious enthusiasm led to many unwise courses. Indications for obstetric operations demanded revision; certainly, they should be more clearly drawn, curtailed, rather than extended. A wise conservatism in obstetrics would be more productive of ideal results than injudiciously used skill. Obstetric teaching was so deficient in most colleges that there should be a sharp and early improvement. So long as obstetric teaching was defective, so long would obstetric results be bad in practice. An obstetric curriculum should be devoted to practical instruction on the mannikin, in the class room, and in clinic; obstetric surgery should be a very small part of the coordinated whole. The proper place of the latter was in postgraduate courses intended for those preparing for the specialty.

A Comparison by Statistical Methods of Certain External Pelvic Measurements of French and American Women.—Dr. FRED L. ADAIR of Minneapolis said that he appreciated fully the limitations of external pelvimetry, but also felt that the value of this method of examination might be increased by better methods of statistical study. The racial and national pelvic differences should be more carefully studied and recorded so that observations made and conclusions drawn in one section of the world might not be applied too arbitrarily in other sections. There were apparently definite pelvic differences, not only in different races, but in different nationalities. This was indicated by the earlier work of La Verneau and Vrolick. It was shown definitely by the work of Williams and his associates in comparing the pelvis of the negro with that of the white, by the studies of Emmons and De Souza, also by those of Acosta-Sison and Calderon. The present study also showed less marked, but none the less definite, indications of national as well as racial pelvic differences which were apparent even on external examination of the living subject. It was obvious that much more accurate deductions could be drawn by more complete and extensive pelvic measurements. He regretted that he had been unable to make these comparisons, but the conditions under which the work was done made it none too easy to secure even the measurements which were obtained.

Forced Labor.—Dr. JOHN O. POLAK of Brooklyn, N. Y., said that in 200 cases of labor in contracted pelvis, recently studied, he found that 81 per cent. were delivered spontaneously, or the labor was terminated with low forceps. This certainly showed that each case of relative contraction was at least entitled to a proper test of labor before the abdomen was sectioned. While the application of forceps to the engaged head in the presence of properly prepared soft parts was admitted to be a most valuable procedure, both in the interests of the mother and the child, when the fetal arrest was due to failing powers—it had its limitation of safety as a routine measure, and definitely increased trauma to the soft parts. Therefore, he felt that shortening the second stage by intervention with the forceps was not justifiable as a routine measure any more than eliminating the second stage and delivering every child whose head would come into the brim by elective version and extraction with no other indication than to eliminate the second stage of labor and thus relieve the woman of the pains and agonies of childbirth; was safe teaching for the student or graduate without months or years of special training. Furthermore, the cesarean section was not without its morbidity and its mortality. Beck showed that there was a 30 per cent. morbidity in his study of 107 cases. Rupture of the cesarean scar was not an unknown possibility, and in his collective study of 2,000 cases done by the leading operators throughout the country, there was a mortality of nearly 10 per cent. and of over 2 per cent. in the elective group. Another procedure that should come up for consideration and comparison, was hurrying the third stage of labor by expression of the placenta with the first uterine contraction after the child had been delivered. This was definitely unphysiological in that it took time for the uterus by its contraction and retraction, to separate and expel the placenta and produce proper uterine hemostasis. While this practice might be safe in the hands of the trained specialist, it was bad practice and bad teaching for the practitioner and for students.

Acute Malignant Endocarditis Complicating Pregnancy.—Dr. PALMER FINDLEY of Omaha reported the case of Mrs. B., aged 30, II-para, seen in consultation with Dr. Malcolm Campbell of Malvern, Iowa, was seemingly in perfect health until early in her third pregnancy when she suffered from pains in ankles, hips, and shoulder joints which her family physician diagnosed as rheumatic arthritis. The tonsils and teeth were not involved, but the nasal passages were occluded with mucopurulent secretions and incrustations which persisted and prevented her from breathing through the nose. This was the only focal infection discerned. She rapidly lost flesh and strength and became extremely anemic and nervous. There were repeated chills with an irregular course of fever ranging to 104° F. Shortness of breath and palpitation of the heart were recorded as early symptoms. The aortic and mitral valves were early involved and later the tricuspids as well. Blood cultures were taken and the *Streptococcus viridans* found. Precordial friction sounds were observed as a late development. The urinary findings were negative until near the end when the urine presented the usual findings of an acute nephritis and this was associated with uremic symptoms; death was preceded by coma and convulsions. For practical purposes acute endocarditis was classified as simple and septic (malignant). These types probably represent varying degrees of the same morbid process according to the virulence of the microorganisms and the resistance of the tissues. The clinical phenomena and anatomical changes did not differ essentially in the various etiologic forms. The septic type was of special interest to the obstetrician in that it was not infrequently found in association with puerperal infections. Clinically, the septic form of acute endocarditis was distinguished from the simple type by the occurrence of chills, irregular course of fever, and the appearance of multiple emboli. Malignant endocarditis was always of bacterial origin and should be regarded as a local complication of a general infection. Because of the fairly frequent association of acute malignant endocarditis with puerperal infections one found this type of cardiac lesion twice as frequent in women as in men. According to Lenhartz, 21 per cent. of all cases of septic endocarditis were of genital origin. It was rare that any other than the puerperal form of genital infection was complicated by septic endocarditis.

The Drudgery of Obstetrics and Its Effect Upon the Practice of the Art, with Some Suggestions for Relief.—Dr. BROOKE M. ANSPACH of Philadelphia stated that while the almost general and universal use of hospitals for obstetric cases had infinitely lessened the drudgery of obstetrics, much was still to be desired in the direction of securing close cooperation between the obstetric

intern and the practising obstetrician. The obstetric intern should not only be permitted, but should actually be trained to examine the woman in labor under his care. Indeed, before she entered the hospital, the patient should be made to understand that the practising obstetrician would call into cooperation with him the obstetric intern. During pregnancy, the obstetrician should be careful to write a full history and make complete and regular notes of visits and examinations, including the results of pelvimetry, the diagnosis of position, etc., which should be sent to the hospital as soon as the patient went into labor. These notes, with perhaps a telephone conversation, would give the obstetric intern the information he required. As a result, he would be better able to look after the patient during the early stages, and would summon the obstetrician when he was needed. In the larger maternity hospitals fresh attendants might be provided throughout labor by a shifting staff of anesthetist, two nurses, and an obstetric intern, every eight or twelve hours. If the period of labor of a patient continued beyond the time allotted to the staff on duty when he was admitted, the notes made by the first staff might be turned over to their successors. By this plan perfect analgesia throughout labor might be maintained by well trained attendants who were unfatigued and thoroughly awake to the necessities and requirements of the case. An elaboration and possibly an outgrowth of this plan would be the association of several obstetricians—men of approximately equal standing and experience in one maternity hospital. Instead of engaging a particular obstetrician to care for her, the patient would enlist the services of the group collectively, stipulating that she would be willing that any one of them should look after her, the choice depending upon the time of her delivery.

The Interpretation of Vesical Symptoms in Gynecological Diagnosis.—Dr. F. E. KEENE of Philadelphia said that because of its intimate anatomic relationship with adjacent structures, the bladder often participates in the pathology of these organs, whether this be in the form of a displacement, neoplasm, or infection. The vesical symptoms arising from such participation naturally varied in degree as well as kind, and depended primarily upon the nature of the pelvic lesion and secondarily upon the subsequent changes either within the bladder alone or in combination with the kidneys and ureters, which might in their turn become involved. Painful urination was usually the manifestation of an infection which might, with ease, be engrafted upon a chronic retention. Hematuria was rarely found in association with uncomplicated benign tumors and when present might be due to small varices in the bladder wall or to minute papillary excrescences of the mucosa in the immediate vicinity of the tumor, both incident to impaired circulation. Consequently, hematuria in association with a benign pelvic tumor should never be considered a secondary manifestation until proven so cystoscopically, for it usually signified a lesion in the bladder or kidney entirely independent of the pelvic lesion. Likewise pyuria, in the absence of an antecedent history of retention or evidences of an infected tumor, was an uncommon secondary event and its presence should be the indication for cystoscopic study to determine the exact nature and location of the infection. Malignant tumors, especially carcinoma of the cervix, frequently produced vesical symptoms due to direct extension of the growth to the bladder or secondary to renal infection incident to incomplete occlusion of the ureters. The majority of cases of acute pelvic infection, associated vesical symptoms presented little or no difficulty of interpretation being due to extension by continuity along the urethra or to direct contact between the bladder base and the diseased structures. Here cystoscopic studies were not only necessary, but often inadvisable. In the chronic cases the presence of persistent bladder irritability was certainly an indication for such investigation to determine the nature and extent of the disease, whether it had arisen as a purely secondary manifestation or was a coincident lesion, independent of the primary pelvic infection and to what degree, if any, the ureters and kidneys were sharing in the production of symptoms. In conclusion, he could not emphasize too strongly the importance of making cystoscopic examinations in all gynecological cases presenting vesical symptoms, even though the condition might seem quite sufficient to explain these symptoms. Not infrequently, by such a plan, lesions would be discovered which were unsuspected and which were of more vital import than those of the pelvic organs.

Hemorrhage from the Nonpregnant Uterus in the Absence of a Neoplasm.—Dr. WILLIAM A. SCOTT of Toronto, Canada, discussed the histology of fibrosis uteri. The majority of cases were of the subinvolution type with thick-walled, hard uteri, containing an excess of elastic tissue. It had been assumed that the bleeding also occurred from small sclerotic uteri as well as from the large soft organ. Moreover, the typical histological findings of fibrosis uteri were not constantly found in all bleeding cases, but might be found apart from bleeding. Therefore, it seemed probable that the bladder was not dependent upon these histological changes. Glandular hyperplasia of endometrium was the most constant finding in cases of bleeding. Bleeding and hyperplasia were likely ovarian in origin.

Ovulation and Menstruation and Postoperative Considerations.—Dr. THOMAS J. WATKINS of Chicago stated that ovulation and menstruation as postoperative considerations were important because many of the pelvic operations affected these functions. The problem of the ovary relative to operative indications concerned the production of ova and corpus lutea. Unanimity of opinion existed relative to conservation of the ovary when conditions obtained which were favorable to reproduction. Opinions varied much in regard to conservation of the ovary for the purpose of production of corpus lutea. The corpus lutea during menstrual life had been proven to be an important part of the endocrine system. The physical changes that took place at puberty and the menopause emphasized the importance of the ovarian function. The usual good health which obtained after the menopause was completely established demonstrated the ability of the endocrine glands to compensate for the loss of the corpus luteum. The problem of atrophy following the menopause was the one of greatest biological importance. Atrophy following the artificial was no more than after the natural menopause, but the latter was beyond our control. More or less atrophy necessarily followed loss of ovarian function, as growth and sustained growth required function. The loss of one lessened the other. Loss of the ovarian function necessarily caused atrophy in the tissues associated with it in function. No clinical or theoretical evidence indicated that excision of the fibroid uterus compromised the life or function of the ovaries unless they were so situated that the operation disturbed their blood or nerve supply. The menopause symptoms following hysterectomy with conservation of the ovaries appeared about the usual time. The ovaries also remained normal in size, determined by conjoined palpation. It had been his custom for many years to leave the ovaries in favorable cases when excising the fibroid uterus. He had had no instances that raised the suspicion of an increased liability of such ovaries to disease. He had no record of ovarian cysts developed in ovaries left after fibroid operations. It was reasonable that they should occur, but it had not been his experience to see them. His experience in the treatment of small uterine fibroids with radium had induced him to generally limit the use of radium to cases past forty years of age; in younger women supravaginal hysterectomy had seemed preferable to destruction of the ovary by radium. The fact that with radium profuse bleeding occasionally occurred before amenorrhea was established, and that cessation of menses and arrest of growth was often temporary in younger women, was additional evidence in favor of supravaginal hysterectomy. The same evidence for and against conservation of the ovary in fibroids was applicable in case of salpingitis, except that in salpingitis the cortex of the ovary was modified by inflammatory reaction. Conservation of menstruation had no value aside from its relation to reproduction. Menstruation was a handicap nature seemed to have been obliged to impose upon woman for the accomplishment of pregnancy. It was a part of the means of recovery of the uterus from the sorrow over the loss of the ovum. His records showed that operations for re-

trodisplacement of the uterus had become infrequent, generally not more than two or three a year. The uncomplicated cases were usually not operated; the operated cases generally had enough pathology to indicate supravaginal hysterectomy.

The Unsolved Problems in Gynecology and Obstetrics.—Dr. W. BLAIR BELL of Liverpool, England, said that the present position of gynecology and obstetrics as a special development of surgery was high. The object of his paper was to point out that, whereas in regard to clinical and surgical technique there was little room for improvement, our progress in regard to essential biological problems was slow. The question as to whether our present methods of education are likely to help the investigator was first considered. The tendency to minimize the importance of biology and to urge the superior claims of hospital study was unfortunate and probably was to some extent accountable for the present position. Today elementary gynecological anatomy and physiology were taught by the clinician and not by the anatomist and physiologist—at any rate, in Great Britain—the result was that the anatomist and physiologist was unaware of the hiatuses in our knowledge. The man who had difficulties to face in practice would, if properly educated, be the person most likely to overcome them. The necessary improvements in educational methods were radical: The clinician should have the right to define the subject matter of the physiological and anatomical courses, and physiology should be taught more in coordination with clinical work. With regard to postgraduate work it seemed likely that the clinical unit and units for group study would give the best results. In the latter part of the paper some of the morphological and physiological problems were briefly mentioned by way of illustration, such as development of genital ducts and atavisms, tuboovarian sacs, bony deformities of the pelvis, neoplastic developments, maleness and femaleness, puberty, menstruation, lactation, menopause, selective sterility, conception and eclampsia.

Perforating Hemorrhagic (Chocolate) Cysts of the Ovary; Their Importance and Especially Their Relation to Pelvic Adenomata of Endometrial Type (Adenomyoma of the Uterus, Rectovaginal Septum, Sigmoid, Etc.).—Dr. JOHN A. SAMPSON of Albany, N. Y., offered the following as evidence that perforating hemorrhagic cysts of the ovary were hematomata of endometrial type: (1) These hematomata, as the uterine mucosa, manifested their "activity" during the menstrual life of the patient. (2) Histologically the epithelial lining of the ovarian hematomata was similar to that of the uterine hematomata, due to the retention of menstrual blood, often present in adenomyoma of the uterus. (3) Periodic hemorrhages occurred in the ovarian hematomata which were similar in gross and histological appearance to that of menstruating endometrium. (4) The chocolate contents of the ovarian hematomata resembled old menstrual blood. (5) In two patients operated upon at the time of the menstrual period, one the day that menstruation was due, and the other the last day of menstruation, the histological changes in the ovarian endometrial tissue corresponded to the phase of the menstrual cycle indicated by the menstrual history of the patient. (6) The fact that material escaping from the ovarian hematomata might give rise to the development of adenoma of the endometrial type in the tissue thus soiled was further proof that these hematomata contained endometrial tissue.

Bacteriology and Pathology of Fallopian Tubes Removed at Operation.—Dr. ARTHUR H. CURTIS of Chicago said that this study indicated that gonorrheal infection was responsible for at least three-fourths of all inflammatory lesions of the Fallopian tubes. Infection with various types of streptococci had been second in frequency. Tuberculosis, exclusive of generalized tuberculous peritonitis, ranked third. Infections with other bacteria, notably those of the colon group, had been less common and less important. With the exception of a few streptococcus infections, bacteria had not been isolated from tubes which failed to show grossly active inflammation. Just as gonorrheal endometritis seldom became chronic, so it appeared that gonorrheal infection of the tubes ran a quickly self-limited course. While it had long been known that gonococci soon disappeared from the tubal mucosa, it was of interest to learn that modern cultural methods failed to yield growth when the entire diseased tube was thoroughly ground and inoculated into culture media, provided two weeks had elapsed since temperature and leucocyte count returned to normal. This test had been performed repeatedly and with unvarying results. He therefore felt warranted in the conclusion that the Fallopian tube was not a focus for chronic gonorrheal infection. Unfortunately this did not exclude the danger of repeated infection from without, or recurrent invasion of bacteria from the chronically infected lower genital tract. The present study sustained previous experience that the colon bacillus did not cause serious tubal disease. *Bacillus coli* was particularly frequent in tubo-ovarian abscess of large size. As a primary cause of salpingitis it appeared to be of little importance. A survey of the pathology encountered in these tubes emphasized that gonorrheal infection primarily involved the tubes, with resultant thickening, nodulation, closure of the fimbriated ends, and pelvic adhesions which were amenable to separation by blunt dissection. In streptococcus infection tubal involvement was usually but a part of the picture. Perisalpingitis was the most frequent type of tubal lesion, although typical salpingitis, notably hydrosalpinx, occurred with moderate frequency. Tuberculosis was very likely to be overlooked if routine histological preparations were not made. When limited to the pelvic organs it was difficult to establish a diagnosis from the gross appearance alone. Unusually resistant adhesions suggested tuberculous or streptococcus infection. Somewhat similar operative measures appeared indicated in streptococcus and in tuberculous salpingitis. In both diseases infection was not usually confined to the tubes; in both, viable bacteria were often still present in the tissues and there was danger of chronic postoperative infection of the ovaries. It was not his desire to suggest definite rules for operative procedure. But with the possible exception of the cervix, and particularly in regard to extirpation of the ovaries, more radical surgery appeared indicated than in gonorrheal infections of corresponding severity.

Torsion of the Cecum with Review of the Literature and Report of a Case.—Dr. SIDNEY A. CHALFANT of Pittsburgh said that volvulus of the cecum was possible only in patients with an abnormally mobile cecum and ascending colon. This occurred in about 1 per cent. of all persons. This type of volvulus was more common under 30 years of age. The symptoms were those of intestinal obstruction. The treatment was surgical. The nature of the operation was to be determined by the extent of damage to the intestine and the condition of the patient. The case was reported in order to point out the fact that torsion of the cecum, while a rare condition, did occur and that it must be considered in making a diagnosis in obscure cases of intestinal obstruction. This was especially the case in patients presenting a history of obstinate constipation with previous attacks of severe pain in the upper abdomen.

Vulval and Vaginal Cancer.—Drs. HAROLD C. BAILEY and HALSEY J. BAGG of New York City stated that until Janeway had instituted the use of imbedded emanation in vulval cancer, the general opinion of gynecologists was that radium had no place in this field, and even recently they had seen a statement to the effect. From a study of the subject extending now for more than three years they must disagree with this opinion, for they knew that the original lesion might be completely eliminated without loss of any considerable amount of normal tissue, without sloughing and with comparatively little pain. They believed that the method outlined was an ideal one for destroying the primary lesion. There was a minimum opportunity for spreading the disease, especially if the insertion of the tubes was preceded by an application of heavily filtered radium, which tended to devitalize the tumor cells. Wherever possible, the radium tubes surrounding the lesion were inserted through normal tissue. It might seem at first thought that the cautery could accomplish as much and in a short time. It must be remembered that the two reactions were dissimilar. The imbedded radium produced a prolonged, gradual, re-

active inflammation, which was effective in checking the extension of the disease. The experience with various doses of embedded unfiltered radium emanation had shown that if the tubes were of 5 mc. strength, the elimination of the tumor was associated with extensive sloughing and prolonged and serious discomfort; whereas the smaller dose of about 0.5 mc., accomplished as much for the removal of the growth, and yet without sloughing and with little pain. Except in the most minute lesion, it was not possible to arrange the placing of the tubes so that all the cancer cells were effectively radiated. Filtered radium to further check the growth of the injured or partly damaged cells was necessary as an adjunct to the implantation of bare tubes in vulval and vaginal cancers.

The Cure of Cystic Cervical Endometritis by the Aid of Multiple Scarification.—Dr. HENRY T. BYFORD of Chicago said that cystic degeneration of the cervix was curable only by a destruction of the degenerated glandular tissue. When it was limited to a small part or parts of the vaginal portion the desideratum was to destroy only the cysts and degenerating glands. Cutting operations and cauterization destroyed too much functionating mucous membrane while the ordinary local treatment consisting of puncture of follicles as they developed and the application of the tincture of iodine was seldom curative. The author employed a modification of this local treatment that made it curative. Instead of using the ordinary lance pointed uterine scarificator only upon cysts as they became apparent, he used a bayonet pointed one and made from 50 to 100 punctures into the diseased area or areas from once to twice a week and made an application of iodized phenol strong enough to destroy or cause atrophy of what remained of the epithelial cells in glands that were already seriously damaged by the inflammatory action, but not strong enough as used to destroy functionating glands. The application consisted of one part each of iodine crystals and glycerin and two parts of phenol. A few treatments were made twice weekly, then once weekly until the surface looked and felt normal. After a few months the patient reported for examination and possible treatment of cystic follicles that had not been reached.

BRITISH MEDICAL ASSOCIATION.

Eighty-ninth Annual Meeting, Held at Newcastle-on-Tyne, July 15-23, 1921.

(Special Report from Our London Correspondent.)

Poliomyelitis.—Dr. G. FARQUHAR BUZZARD of St. Thomas's Hospital, London, read this paper in the Orthopedic Section. Perhaps the most interesting part of the paper was that in which he discussed the similarities and differences of poliomyelitis and encephalitis lethargica. It was pointed out that we are now faced with two infective diseases of the central nervous system in both of which the chief incidence of inflammatory action may be cerebral or spinal. In that disease, for which the virus of poliomyelitis is responsible, the spinal cord is more often attacked than the cerebrum. But polioencephalitis and poliomyelitis are not uncommonly present in the same patient, or in epidemics especially a certain number of individuals only display symptoms referable to inflammation of the higher centers. Practically all cases of lethargic encephalitis present cerebral symptoms and signs, but a small minority are characterized by evidence of spinal cord involvement as well. Buzzard drew attention to the fact that from the etiological point of view poliomyelitis is a disease of infants and children, the incidence rapidly declining as age advances. It prevails chiefly during the summer months, is acute in its onset and runs its course in a few days. Lethargic encephalitis, on the other hand, attacks impartially persons of all ages. It is more prevalent during the winter and varies enormously in its mode of onset and in the duration of its attack. Although the presence or absence of any particular symptom or sign is insufficient to differentiate the two diseases, seeing that inflammation of any part of the central nervous system is a factor common to both; yet there are certain features in many cases of lethargic encephalitis which are to some extent characteristic. These are lethargy, the mid-brain symptoms, and the involuntary movements and muscular contractions which have drawn so much attention to the disease.

Radiology in Diseases of the Blood.—Dr. G. LOVELL GILLAND of the University of Edinburgh read this paper. He pointed out that there is one disease of the blood in which radiation deserves a much more systematic trial than it has yet received, polycythemia vera, or Vaquez's disease. Its main features are a great increase of the circulating red corpuscles, often to double the normal number or more with high blood pressure, and usually with enlargement of the spleen. The cases are very rare, and since it occurred to Gulland to try radiation for them he has only seen one case. In this a course of *x*-ray treatment was commenced, but had to be stopped for family reasons. The marrow in this condition is unduly active, and it is possible that radiation of the long bones might be useful in checking the increased output of red corpuscles. According to the author the most favorable form for radiation is chronic myelocythemia, and in regard to this disease a very large amount of experience has now been accumulated. Some time ago, as he was disappointed with the *x*-ray results, he began treating all his cases with radium, and, while he cannot say that the benefit produced has been any more permanent, it has been more certain and rapid, and it has seemed to him that the patients improved more in general condition, and especially in recovering from their anemia. The amount of radiation required varies greatly in different cases, partly because of the different periods in the disease at which treatment is begun, partly because of the general condition of the patient and probably because of unknown factors also. He is accustomed to regard a leucocyte count of 20,000 as the signal for stopping radiation, for the effect goes on for some time after radiation has been stopped, both as regards the white count and the diminution in size of the spleen. In Gulland's opinion the reason why the myelocythemias are so much more amenable to radiation than the myeloblastemias is that the cells affected are of a much more differentiated type, they approach more nearly to a benign tumor. It is evident from the progress of cases that many of the circulating leucocytes are destroyed, and that the rays also arrest their development. For this latter reason radiation of the long bones in turn is sound, both theoretically and practically.

PROFESSOR SIDNEY RUSS remarked that a study of the effects of *x*-rays upon the circulating leucocytes of the rat has shown that whereas for a certain measured dose of *x*-rays the effects upon the lymphocytes are regular and can be repeated, simultaneous observations upon the polynuclear leucocytes show that here the changes produced are quite irregular, for an increase or decrease may occur in their numbers as a result of exposures to radiation. These outstanding differences in behavior are illustrated by blood counts upon the same batches of animals. Observations have also been made upon the effects of exposure of the body to rather large quantities of gamma rays. In this case blood counts were made immediately before exposure to the radiation which lasted for some hours: counts were then made two and seven days after the exposure. Here again it was found that a greater regularity was observed in the behavior of the lymphocytic than in the polynuclear forms.

Protection Against Radium and Roentgen Rays.—Dr. J. C. MOTTRAM, discussing the use of blood counts to indicate the efficiency of *x*-ray and radium protection summarized as follows: (1) That a single blood examination may give warning of danger if the count be near the low limit for normals. (2) That a considerable fall with a sustained low level in the repeated blood examinations of a single individual indicates that insufficient protection is being provided. (3) That if several workers in the same department present very low counts, this also shows that further protective precautions are required. (4) That in workers using soft *x*-ray radiation special attention should be paid to the lymphocytes, because these cells are more likely to be affected than the polynuclears or red cells. Mottram concluded by saying that it is to be regretted that rulings more precise than the above

cannot be laid down, but that this will not be possible until further data in respect of both normal individuals and *x*-ray workers have been collected.

Treatment of Gonorrhea.—Mr. DAVID LEES, Surgeon to the Venereal Diseases Department of the Royal Infirmary, Edinburgh, read a paper on the treatment of gonorrhea in men. The paper was very long and can be referred to but briefly. As for general treatment, the speaker pointed out that this aspect of the therapy of gonorrhea is chiefly of importance during the acute stage. As in all inflammatory suppurating conditions, cleanliness, rest, simple diet, and the essential acting of all the excretory organs of the body are necessary. Alkaline diuretics combined with urinary sedatives are of greater value than any of the more reputed specific drugs, and much less harmful to the general condition. The combination of the sedative action and the mechanical flushing of the urinary tract outwards as a results of diuresis, by increasing the amount of urine and the frequency of passing it, is the safest and best means of cleansing the tract. There is, in the view of Lees, no appreciable danger in alkalinizing the urine if the drug is not exhibited over too long a period, and on an average seven to ten days is a sufficiently long period over which to induce this diuresis. The speaker went on to point out that there are few, if any, other drugs required in the treatment of any case of gonorrhea running a normal course. In the complications, however, and during the instrumental treatment necessary often as the result of the action of the gonococcus on the urinary tract, drugs, such as urotropin, salol, boric acid, etc., are of value, but should not be given in doses which will set up urethral irritation. Urotropin is a good example of this and gr.v to gr.vii, three times a day, is sufficiently large for almost any case. There are also certain drugs, such as ichthyol and atropine and opium, which are helpful in prostatic and epididymis complications, while in joint complications iodides are often advantageously exhibited. The only successful method of eliminating the gonococcus from the deeper tissues and the many side-tracks where it is certainly inaccessible to antiseptics is by increasing the antibody response. Numerous workers in America, in Europe and in Great Britain have so perfected the complement fixation test as to be able to estimate this antibody response, but few of these workers are agreed in the estimate they form of what this response means in relationship to cure. In his experience a rapidly increasing and high antibody response seen serologically is coincident with rapid clinical improvement, and the test is of value in diagnosis, in control of the administration of vaccines, and in the determination of cure. If the ideal treatment is to be attained, Lees is convinced that it will be along the lines he has indicated, by the use of mild antiseptics applied to the inflamed part in combination with the administration of a strongly antigenic and specific vaccine; but the clinician must have working with him a competent bacteriologist or serologist to help in working out more accurately the methods of administering specific vaccines and of controlling their actions.

Syphilis in Women and Children.—Dr. WALTER C. SWAYNE of the University of Bristol read a paper on this subject. He emphasized the importance of the family doctor in the treatment of the disease, pointing out the venereal clinic should not be the only avenue of attack on the disease. Early diagnosis and continuous treatment are most important, and the cooperation of the family doctor is necessary for any real advance. Diagnostic difficulties are not greater than they were in years gone by, but diagnostic facilities are now much increased. The technic of modern methods of treatment is not difficult and can quite easily be learned if time is available. The family doctor can with great advantage treat a large number of patients now attending clinics. Clinics should be much more largely consultative for diagnostic purposes, and should be used for such treatment as the family doctor feels he is not able to undertake, either on account of lack of time, or any other reason which may seem good to him. The foregoing remarks apply especially to syphilis in women, the majority of whom will avoid the publicity of a special clinic, and a large proportion avoid consulting any medical practitioner at all. This is often from lack of knowledge of the possibilities of infection and the possible immediate and remote results. There are obvious difficulties in the recognition of primary symptoms by the patient herself, and if the site of infection is within the genital canal this is not possible. Swayne summarized the situation as regards syphilis in women as follows: (1) There are greater difficulties in women than in men, owing to the frequent failure of the patient to detect symptoms in herself. (2) A very large number of those affected contract the disease innocently. (3) Women are, on the whole, more likely to act as innocent carriers than men, especially of extragenital infections. (4) Diagnosis is on the whole, more difficult with women than with men. (5) Treatment is often interfered with by home duties, conditions of employment, pregnancy, and parturition. (6) The special social and family surroundings of women make the disease in their case more difficult to deal with, and perhaps of more importance than in the male. (7) Quite a large proportion of women suffering from syphilis come, sooner or later, into the hands of the gynecologist for the treatment of various pelvic affections.

The Standard of Cure in Gonorrhea.—Dr. E. R. TOWNLEY CLARKSON read this paper. He laid stress upon the point that it is of the utmost importance that the microscopical and bacteriological examination should be carried out by an expert. The practice which sometimes obtains of these examinations being made by practitioners possessed of but slight experience in such highly technical procedures is to be condemned. Such an action is unfair to the patient and may be productive of injury to others. It is also impolitic, inasmuch as the false verdict of an amateur may be followed by a recurrence of the original trouble and the defection of the patient. If the practitioner is not accustomed to obtaining the necessary specimens it is better for him to secure the presence of the bacteriologist for the purpose. The speaker said he was well aware that most of his hearers placed but small reliance upon the bacteriological and microscopical examination as constituting a necessary factor in testing patients before discharging them as cured. Their contention was that all necessary information could be obtained by skilled clinical examination and observation. On the other hand, there were those so influenced by bacteriological and microscopical methods that they were in danger of employing these in a manner verging on the mechanical, and through a lack of experience were tempted to evaluate clinical examination very lightly. A lesson may be learned here from the annals of syphilis, which tell of the brilliant results which were obtained by experienced clinicians before spirochetes were thought of and when the Wassermann reaction was unknown. Just as competent syphilologists now regard the clinical and laboratory findings as complementary in relation to the investigation of syphilis, so it is equally rational to cull and judiciously interpret all information which can be obtained from these two provinces in respect to the determination of the cure of gonorrhea.

The Dysergy of Scorbutus.—In addition to the frank symptoms of scurvy we should know the latter through its predisposing to other affections. Abels in the *Wiener klinische Wochenschrift* for October 7, xxxiii, 41, calls attention to this predisposition *dysergia scorbutica*. Subjects deprived of antiscorbutic vitamines are greatly predisposed to various infections and it is the infection which may be responsible for the hemorrhage. The reactions of this dysergia are paradoxical and incomplete. Such a problem should be solved by the aid of animal experiment for by placing the animal on a scurvy diet it should be easy to produce infections of hemorrhagic type. This has now been worked out by Abels. Guinea pigs were rendered scorbutic by an exclusive diet of cereals and water. When in this condition they were readily killed by injections of coli cultures, which ordinarily they could withstand. Injections into the derma, lymphnodes, muscles, etc., of cultures of staphylococci caused hemorrhages, although in the guinea pig scurvy, spontaneous hemorrhages are of rare occurrence.

Miscellany.

Guy Patin.—This ancient medical worthy of France could not visualize the possibility of progress in his profession. He refused to believe in Harvey's discovery and other innovations of the period. Bloodletting and purgation he practised but all powerful drugs like opium were for him only so many dangerous poisons, the use of which in medicine was a crime. He inveighed against his colleagues who "grew rich through poisoning their fellow creatures." It is not surprising that he abandoned his first profession for literature, and this without regret. As a writer his correspondence was not highly regarded by Voltaire. Pic made a compilation from his writings which was a success, but regarded the author as much overrated and shallow. But since he was not writing consciously for the public his writings have the value which attaches to that class of publication. Critics who came after Voltaire were more favorable to Patin. Sainte-Beuve commended his good sense, and amusing "pep," and his very notions, prejudices, freedoms of speech, inconsequences, and mannerisms confer an originality upon him as an epistolary chronicler of the manners of the time. His most recent editor is Andre Thèrive, who has just published a volume entitled "Guy Patin. Lettres du Temps de la Fronde," which is one of a series of "overlooked masterpieces." It comprises selected epistles which relate to the days of the Fronde and the editor styles his subject a ready writer who is not correct but whose prattle is agreeable and natural and who smacks of the native soil. —*Le Progrès Médical.*

A New Biographical Work on Laennec.—Long before the Laennec Centenary his chief biographer, Rouxeau, had begun to publish his work along this line, largely from unpublished documents. The earliest volume appeared in 1912 and dealt with his subject up to the year 1806, or during the periods of childhood and youth. The second volume has recently appeared and is entitled "Laennec after 1806" covering the period 1806-1826. The documents comprise many letters to his father, Uncle William, relatives, and friends. At the beginning of the period he was but 25 years old, resident for several years at Paris and already very prominent in the public eye. He was on the University Faculty, editor of a medical journal, and member of the leading medical society of France. As an anatomist he had discovered the subdeltoid bursa and the fibrous capsule of the liver; he excelled as an operating surgeon, and as a diagnostician he seemed to have a special clairvoyance. He was the first to discover and describe peritonitis, he discovered also acephalocysts, and gave the first good description of melanotic tumors. His work on pathological anatomy was a masterpiece which he was never able to have published. Already he had been termed the Bichat of pathological anatomy. Before long he was on the staffs of three medical periodicals and showed enough journalistic ability alone to have made his name distinguished. In controversy he refused to yield an inch. But despite his eminence he was terribly poor and even when the period opens he was making but 400 francs a year from his practice with a small addendum from the *Journal de Médecine* of which he was sole owner. He thought his practice ought to yield from 1800 to 2000 francs, which shows how far he stood behind his modest ambition.

There were the usual disappointments. Two much-coveted salaried posts which might have made him went elsewhere. There was nothing to do but stick to practice. He joined the staff of a free dispensary. Quite unexpectedly he was appointed through a friend to be personal physician to a cardinal of the Church and was obliged to borrow the money to make himself presentable for his new berth. This sum of 700 francs was evidently in excess of his entire annual income at the time. The amount was well invested, for the position gave him prestige in the eyes of the public. From 1808 his income steadily mounted, and by 1813 it had reached 10,000 francs. His clients were largely people of distinction, and this nearly proved his ruin, for in 1814 there was a sudden exodus of society to the country, probably connected with the reverses of the French armies. During the next two years he barely "broke even," and when the clientèle returned they seemed to have forgotten him completely, as he was unable to keep up the appearance of the successful practitioner, including the private carriage which alone meant an expense of 300 francs a year. He tried to get money from home, with but little success. Since 1803 his lungs had been troubling him, and his inability to rest in the country coupled with his enormous mental industry was beginning to tell on him. He had now become a hypochondriac dyspeptic. His portrait, painted by Dubois in 1812, looked like that of a dying man. At last he was forced to take a brief vacation, which did him a world of good, and he began to think of removing permanently to his native Brittany. Two more tremendous years of work, with the loss of his fashionable practice and the death of many of his old friends and well-wishers, finally made the choice for him, and he returned to the paternal roof, where he was badly needed to save the estate from its creditors. Thus began the last chapter of his life. —*Le Progrès Médical.*

Official Report of the Influenza Pandemic in Cuba.—This report, made by Dr. Le-Roy y Cassá, appears in *Sanidad y Beneficencia.* The epidemic appeared in October, 1918, and spread rapidly over the island. Of similar episodes in the past we have records of but two, the epidemic of "dengue" in 1828, which was almost certainly not influenzal, and that of undoubted influenza in 1889-90. In only a few months of the time since this 1890 pandemic has there been a total absence of influenzal deaths, so the disease may be regarded as endermic in the island. In May, June, and July, 1918, there was an epidemic coinciding in point of time with the first pandemic wave in Europe, but apparently quite unconnected with it. Between July and October there was no suggestion of epidemicity. The duration of the recent pandemic was from October, 1918, to April, 1919, when it had abated to the normal rate. During this period there were 6260 victims of the disease, of which considerably over one-third occurred in the month of November alone. As the estimated population of the island is more than 2,800,000, the mortality was 22.32 per 1,000 inhabitants.

THE PRESENT STATUS OF NONSPECIFIC PROTEIN THERAPY.

BY HENRY SMITH WILLIAMS, M.D., LL.D.,

NEW YORK

A STRIKING landmark of contemporary progress is furnished by a series of articles in recent numbers of the *Journal of the American Medical Association* dealing sequentially with Serum Therapy, Vaccine Therapy, and Nonspecific Protein Therapy. That a conservative journal should have thought it expedient to give such recognition to Nonspecific Protein Therapy, and with the full authorization of the ultraconservative Board of Pharmacy, only a little over five years after the general theory of the nonspecific protein response was first propounded, bears witness to the astonishingly rapid progress of this newest comprehensive method in scientific medicine.

What, then, is today officially conceded, by the most conservative observers, to Nonspecific Protein Therapy?

First of all, and in general terms, a place in the therapeutic hierarchy in full coalition with Serum Therapy and Vaccine Therapy. In more specific terms, recognition as a therapeutic agency that has been extensively tested and not found wanting (1) in acute infections, including typhoid fever, diphtheria, anthrax, typhus fever, pneumonia, and acute sepsis; (2) in arthritis, acute, subacute, and chronic; (3) in various urological and dermatological maladies, including gonorrheal complications, syphilis, lupus erythematosus, exfoliative dermatitis, and psoriasis; and (4) in iritis, trachoma, and tuberculosis. Mention is also made of the fact that nonspecific proteins have been used for treatment of sarcoma and carcinomas.

An interesting list, assuredly. Taken by itself it quite adequately justifies my prophecy of October 2, 1915, that the protein response would be found to be a resource against all types of protein toxemias, including bacterial invasions. It tends also to validate the prediction made in a monograph published in December, 1916, and reiterated in my book, "The Proteomorphic Theory and the New Medicine," to the effect that:

> Protein therapy, of proved value in conditions ranging from anemia and intestinal toxemia to typhoid fever and tuberculosis, and from rheumatism to cancer—a method, in short, that combats every form of protein toxemia by fortifying the bodily defensive and offensive mechanism as represented in blood forming organs and blood corpuscles—may without exaggeration be said to constitute the most general and the most comprehensive procedure known to modern scientific therapeutics.

The idea that actuated my original suggestion that the use of non-bacterial proteins might supplant the use of serums and vaccines developed from the conception that the observed action of the latter is perhaps largely due to their protein content, as such, even when it is supposed to be a specific action.

This conception in turn was based on my direct observation of the response of the organism to non-bacterial proteins—specifically, sheep serum and plant proteins. These observations, interpreted in the light of the new conception of the physiology of the blood corpuscles (which I had put forward under title of the Proteomorphic Theory) furnished the foundation of the structure now assuming significance as Nonspecific Protein Therapy.

By way of anticipation, I may say that the term "nonspecific" is unsatisfactory. I shall elaborate the point before I am through, but it seems well to retain the term here to avoid confusion.

My personal observation of the value of non-bacterial proteins was fortified by a survey of the literature leading me to the conclusion that a large number of workers for many years in the past have practised Nonspecific Protein Therapy without knowing that they were doing so. I called attention to this and used the inference, with specific illustrations, to fortify my belief that the profession has been gradually and unconsciously working toward the principle that I now generalized in the monograph of December, 1916, and in my book. The conservative expositors whose work is now under review concede the validity of this deduction in these words:

> Then came the recognition that older therapeutic agents belonged to the same category—serums, nuclein injections, the use of yeast, tuberculin, Beard's use of trypsin in carcinomas, or the use of Coley's fluid in sarcoma.

The "same category" referred to is:

> Protein split products—proteoses, bee toxin, pollen, etc., milk injections (intramuscularly), and extracts from tissues.

Having gone so far, however, the conservative reviewers curiously stop, and make no further mention of the nonspecific protein treatment of cancer, although that is at once the most important field to which the method has been applied and the one in which it has been most extensively and convincingly tested. It is equally to be regretted that limitations of space or failure to apprehend the true character of the protein response led the reviewers to fail to present, except by the most cursory references, the well established facts as to the applica-

tion of the method to the allied disturbances of metabolism which for the average adult are so much more important than acute infections.

This omission causes anyone who fully apprehends the problem to feel, on reading the three articles devoted to alleged summary of the status of nonspecific protein therapy today, that we are given a report comparable to that of the traditional three blind men who examined the elephant—grasping trunk and leg and tail respectively—one pronouncing the animal like a snake, one like a tree, one like a rope. We get reports on foreign protein therapy in acute infections, in arthritis, in certain urological and dermatological maladies—the trunk and legs and tail of the elephant—but only vague reference to the great groups of disorders of disturbed metabolism—from anemias and leukemias to tuberculosis, from intestinal toxemias to arteriosclerosis, albuminuria, glycosuria, asthma, goiter, and cancer—that constitute (still holding to our symbol) the body of the elephant.

However, it is much to have the principle of the general protein response recognized as a tangible entity. At least the blind men know now that an animal is there—and a very big animal. In time the animal will be revealed to them in its true dimensions, form, and proportions.

Meantime, let us attempt a brief orientation of the subject in its comprehensive aspects—including trunk, legs, and tail, if you please, but not forgetting the head and body. In other words, let us summarize the facts at present available as to the therapeutic value of Nonspecific Proteins as applied in the two great groups of maladies which, roughly speaking, may be said to constitute the field of the physician's activities, namely: (1) microbic infections and (2) disturbances of metabolism more or less independent of microbic action.

Nonspecific Protein Therapy and Microbic Infections.—In considering this phase of the subject we must bear constantly in mind an elementary fact that is often overlooked even by bacteriologists; the fact, namely, that every specific infection involves a nonspecific element. That is to say, the acute or chronic illness resulting from a bacterial invasion—diphtheria, typhoid fever, pneumonia, or what not—involves the invasion of the body by an actual physical company of protein-bearing organisms, which may be visualized as an army. These organisms, if left unchecked, would multiply with such rapidity that within a few hours they would inevitably clog the entire blood stream and cause the death of the patient even if they were otherwise entirely innocuous.

In this view, the invading microbes are nonspecific proteins. They must be considered as actual physical invaders to be combated by the bodily defenders if the host is to escape overthrow.

But these nonspecific protein invaders in the course of their development give out by-products that are poisonous to their host. It is not that they should be likened to an army that sends ahead of it poisonous gases; but rather to an army that in the very nature of things through its existence gives out excrementicious matter—sewage, garbage —that makes the environment unwholesome; infecting the soil and the water if you please.

These poisonous by-products are inseparable from the growth of the organism; they differ slightly among the different organisms even of allied species, and they constitute what we are accustomed to speak of as the specific toxins of disease. These toxins must be neutralized or the human host will suffer. In the case of such an organism as the diphtheria bacillus, which chiefly grows on the mucous surface, sending its by-products into the blood—in effect using the human vascular system as a sewage system—the specific toxin appears to be the more potent influence; but it must be obvious that in every case the organism itself precedes the by-products; and it follows that if means were available to destroy the organism promptly, the danger from its toxin would be negligible.

In other words, we are presented with what at first seems the paradox that if the nonspecific element in the microbic invasion could be promptly destroyed or removed, there would be no occasion to consider the specific element.

The truth of this proposition is at once manifest if we consider the concrete case of effective antiseptic or aseptic surgery, in which by physical removal or exclusion of the bacterial protein bodies all danger of development of toxicity in the patient is prevented. Similarly, if one could promptly remove any diphtheria bacilli that found lodgement anywhere about the mouth or pharynx of the patient, there would be no occasion for the use of a specific antitoxin. The same thing is equally true, quite as obviously, of the germs of typhoid fever or of pneumonia or of tuberculosis or any other pathogenic organisms that may enter the buccal or nasal passages.

It is obvious also that, in lieu of mechanical removal of these invaders, the same purpose would be served if the mucous surfaces themselves secreted bactericidal fluids; or if the blood and body fluids of the patient contained bactericidal or antitoxic enzymes; or if the phagocytic blood corpuscles were adequate to engulf and destroy immediately any microbes that found their way into the parenteral system.

In point of fact, these conditions may be met adequately in the case of the normal human organism, as proved by the fact that most individuals go about in an environment more or less inhabited by pathogenic bacteria, and yet escape illness. We say of such individuals that they are immune to the attacks of the pathogenic organisms in question. To cite a specific case, we now know that a high percentage of infants are immune to diphtheria. The Schick test utilizes diphtheria toxin and antitoxin to test the individual as to immunity, and, incidentally, to enable us to develop immunity in the susceptible.

Suppose, however, that the body of an individual not possessing such natural immunity is invaded by the pathogenic germs—let us say Klebs-Loeffler bacilli—which find lodgment and a nourishing soil in the fauces. They multiply rapidly and, their excreta being absorbed into the blood stream of the patient, a condition of intoxication is produced characterized by symptoms pathognomonic of the disease we call diphtheria. The conventional thing to do then is to practise specific serum therapy; inoculating the patient with so-called antitoxin which, as everybody knows, is developed by inoculat-

ing a horse with diphtheria toxin and ultimately securing blood-serum containing the antidotal substance developed within the organism of the animal.

The relative efficacy of this method of treatment is quite beyond question. Specific serum therapy as thus exemplified is used for the salvage of human life all over the world, and untold thousands of individuals owe a tribute of gratitude to the genius of Von Behring, the father of serum therapy.

A moment's consideration makes it clear, however, that the use of an antitoxic serum involves not merely specific therapy (the neutralization of a specific bacterial toxin), but also nonspecific protein therapy, in that the proteins of the blood serum of the horse are administered along with the antitoxin which as yet we have no means of isolating.

In the light of the new knowledge as to the protein response it becomes a highly interesting question as to what share in the benefits derived by the patients from an injection of antitoxic serum is to be ascribed to the antitoxin itself and what share to the nonspecific serum proteins. The latter unquestionably have a physiological effect. Every practical physician knows of the danger of violent reactions of the type called anaphylactic. Such reaction, associated with leucocytosis and presumably with an increase of phagocytic and enzymic activities, is now recognized as being of value for the patient in combating various infections.

May we not plausibly assume, then, that the horse serum, hitherto considered as an excipient for the antitoxin, is in itself a therapeutic agent of value in stimulating the bodily defenses against the Klebs-Loeffler bacillus? If so, we are meeting the nonspecific protein invasion (represented by the bodies of the bacillus) with a nonspecific protein antigen (the protein of the horse serum), while at the same time we meet the specific toxin invasion with a specific antitoxin.

Carrying the argument a step farther, might it not be possible, particularly at an early stage of the invasion, to utilize the nonspecific antigen alone (the normal horse serum) to vanquish the bacterial invaders before they have time to secrete any considerable quantity of toxin? If so, we should have nonspecific protein therapy substituted for specific serum therapy—the *possibility* that I clearly suggested when I first put forward the theory of the general protein response thus becoming an *actuality*.

When we read in the series of papers referred to at the beginning of this article of the use of nonspecific proteins to combat "typhoid fever, typhus, pneumonia, diphtheria, anthrax, acute sepsis, tuberculosis, and syphilis"—as listed by Dr. Joseph L. Miller—we cannot avoid the feeling that the prophecy, which no doubt seemed fantastic to most readers when presented, is well on the way toward fruition. The correctness of my original contention that we had to do with a general protein response quite independent of the particular character of the proteins, so long as it is foreign to the individual organism under observation, is emphasized by Dr. Miller's statement that: "The results in the treatment of typhoid are quite uniform, regardless of what particular form of foreign protein is used;" by sundry references of a similar implication, and indeed by the necessary implications of the entire series of articles.

Moreover, Dr. Miller cites Bingel as reporting "a series of 466 cases of diphtheria treated with normal serum in which he claims that the results were as satisfactory as in 471 controls receiving antitoxin serum;" and although the validity of the inference is not unchallenged, it is admitted that the results suggest "some benefits derived from normal serum," and that "at least certain normal serums possess considerable antitoxin properties."

This, after all, is no more than might have been inferred *a priori* (since all we can expect of any organism is the accentuation of enzymic activities already existing, not the creation of new potentialities), but it is of importance always to have theoretical inferences sustained by practical observation.

To the same end we may note that "Myer reports $33\frac{1}{3}$ per cent. of guinea pigs saved after receiving a lethal dose of diphtheria bacilli, as compared with 100 per cent. saved after antitoxic serum." Again, "Kastenmeyer states that three animals receiving one hundred times the fatal dose of diphtheria toxin were saved with normal serum." Also, "most striking are observations made by Kieus and Kenna in the treatment of anthrax in man with normal beef serum given either subcutaneously or intravenously in dose of 30 to 50 cc. They report 146 cases so treated with one death; results better than had been reported with the use of immune serum."

Such results, accepted and quoted by conservative observers, appear to substantiate the suggestion that the use of specific serum therapy involves, whether or no, the application of nonspecific protein therapy as well. Whether the nonspecific treatment alone would suffice depends, probably, upon the stage of the development of the malady and therefore the degree of toxin invasion. It takes nothing from the force of the evidence to concede, with Miller, that, pending further laboratory study, "no physician would care to assume the responsibility of administering a foreign protein in diphtheria in lieu of antitoxic serum."

I would supplement this testimony of various independent workers with the following comment: It is my personal opinion, based on wide experience, that vegetable proteins, relatively devoid of toxicity, and partially hydrolyzed to eliminate the danger of anaphylaxis, are preferable to animal serum (or to milk proteins and egg proteins, which also I have tested extensively) for the general utilization of the nonspecific protein principle. I have suggested the generic name *Proteïls* for the nonspecific animal proteins and the allied word *Proteals* for the vegetable proteins. I do not affirm that there may not be cases or types of maladies in which the animal extracts are superior. But my personal experience and the experience of several hundred physicians who have co-operated in testing nonspecific proteins prepared in my laboratory, justifies high confidence in the proteals and proves that they have a wide range of application both in infectious maladies and metabolic disturbances.

Not to get ahead of our story, however, a few words must be said about the interpretation of certain well-known phenomena of the second member of the ultra-modern therapeutic triumvirate—vaccine therapy.

Nonspecific Protein Elements in Vaccine Therapy.

—Properly interpreted, vaccine therapy is only serum therapy in which the human organism is made to develop its own antibodies (antitoxins, bactericides, bacteriolysins, opsinins, agglutinins, according to the usual terminology) instead of having this work performed vicariously in the body of a horse or other animal. Practically, we inoculate a patient with a quantity of dead bacteria, introducing thus the bacterial proteins together with their endogenous specific toxins.

Personally, I regard this procedure as illogical and as necessarily in some measure harmful. It is unpleasantly like administering more morphine to a patient who is suffering from morphine poisoning.

It is conceivable that the benefits from the protein in the bodies of the bacilli (through evoking a typical nonspecific protein response) may more than counteract the harm done by adding more toxin to a system already struggling against toxin of the same type. But a far more logical procedure, it seems to me, is to introduce the nonspecific proteins altogether dissevered from any specific toxin. To that end, one may advantageously discard the vaccine and substitute foreign proteins of altogether different origin—normal serums of horse, or ox, or sheep; or still better, in my opinion, vegetable proteins extracted from nontoxic seeds such as those of alfalfa, clover, millet, rape, and numerous others.

If this reasoning is valid, vaccine *therapy* as practised in recent years is now an anachronism—or at least a method open to challenge. It is a questionable procedure, and vaccines as *therapeutic* agents have doubtful place in the equipment of the physician. My suggestion of six years ago that nonspecific protein therapy would perhaps supplant vaccine therapy altogether is, I believe, by way of being realized in the present.

But if this applies to the specific use of vaccines (antityphoid vaccine, for example, in the treatment of typhoid fever), it applies with almost equal force to the use of the same or similar vaccines in carrying out an alleged nonspecific protein therapy. To administer some millions of bodies of typhoid bacilli, and along with them an increment of typhoid toxin, to a patient suffering, let us say, from arthritis, on the ground that you wish to introduce a foreign protein—and that alone—into the system, is about as logical as to mix in a toxic dose of morphine or strychnine when administering quinine to a malaria patient. It suggests the use of a bludgeon as an adjunct to ether in producing anesthesia.

It will be understood by every thoughtful reader that in all that has just been said no reference whatever is intended to the use of the vaccines in question as *immunizing* agents. It must be clear to everyone having the slightest conception of the nature of immunization that to introduce the dead bodies of bacilli together with their toxins in order to evoke a systemic response both nonspecific and specific, that the individual organisms may be put in a position to offer immediate defense against the possible future invasion of living bacteria, may be an altogether logical and highly commendable procedure; whereas the introduction of the same vaccine into the system of a patient already suffering from an invasion of the living bacteria might be harmful instead of beneficial.

In other words, we should discriminate sharply between vaccine *immunization* and vaccine *therapy*. The former stands as a perennial tribute to the genius of Sir Almroth Wright; the latter represents the misapplication of a method that is at least open to question.

So much for the trunk and legs and tail of our therapeutic elephant. Now let us make a very brief survey of its body and vital organs.

Nonspecific Protein Therapy and Conditions of Disturbed Metabolism. — This more important aspect of the subject is treated in detail in my earlier writings, notably two articles in the *New York Medical Journal* (October 2 and November 13, 1915); in a monograph titled "The Proteal Treatment of Cancer and Allied Conditions," issued in December, 1916; in a book of more than 300 pages, "The Proteomorphic Theory and the New Medicine," issued in March, 1918; and in two articles in the MEDICAL RECORD titled "A Year of Proteal Therapy" (November 22, 1919) and "Theory and Practice of Proteal Therapy" (December 20, 1919). The last named articles, as the titles imply, deal chiefly with the vegetable proteins (being mainly concerned with a review of my own work, which has been chiefly, though by no means exclusively, concerned with the vegetable proteins), but having purview of the entire subject, as implied in the opening sentence of the first article: "What are the applications and limitations of nonspecific protein therapy?"

As to how the question was answered, I must refer the reader to the articles themselves, or to the book, which is still, I believe, the only comprehensive work on the subject in any language. The MEDICAL RECORD articles—constituting by far the most comprehensive treatment of nonspecific protein therapy that has appeared in periodical literature—supplement and extend the evidence presented in the book, for the value of the method (chiefly as exemplified in the use of nontoxic vegetable proteins) in combating an extraordinary range of maladies associated with disturbances of metabolism.

As the pamphlets in which the text and tables of these articles are reprinted bulk more than ninety pages and yet profess to give only a summary of the subject, it would obviously be folly to attempt even an epitome of their contents here. Nor can I attempt to present even an outline of the newer evidence as to the value of the method in most of the conditions mentioned and in sundry others—including specific urethritis and syphilis—that has come to hand through my personal observations or reports received from cooperating physicians during the intervening months.

Instead I must content myself with a few recapitulatory statements lacking which the present article might not be clearly intelligible to physicians who have not seen or cannot now secure access to the literature above mentioned. For the benefit of such readers I would state that my pioneer work in nonspecific protein therapy has included the practical use of bacterial vaccines (to a limited extent); animal serums, in particular sheep serum; proteins of milk and of egg albumin; and (notably) a wide range of vegetable proteins principally ex-

tracted from the seeds of alfalfa, millet, rape, mustard, clover, hemp, and cotton, but including first and last about a score of other plants, and various food proteins.

The protein extracts have been prepared of various strengths, but for the past four and a half years the standardization in my laboratory has been (for plant proteins, for which, as already mentioned, the name proteals has been suggested) on the basis of three milligrams of nitrogen to the cubic centimeter, representing therefore approximately a two per cent. protein solution. Some of the extracts, notably that of alfalfa proteins, have lent themselves readily to the production of a solution of double strength (approximately four per cent. protein). The solutions of egg and milk protein were standardized on the basis of approximately three per cent., as they seemed less potent than the vegetable proteins. For these, along with the other animal proteins, I have suggested the name proteils. Various horse serums and sheep serums, including those believed by their developers to contain antibodies against goiter, cancer, etc. (but in which, in my view, the action is at least partly that of nonspecific proteins) have been found to contain from six to ten per cent. protein, being therefore considerably more concentrated than the normal vegetable extracts prepared in my laboratory.

The vegetable proteins originally utilized comprised the unbroken protein molecule, and with them there was the possibility of producing an anaphylactic reaction. During the past five years, however, a method of preparation has involved boiling the ground seed in dilute hydrochloric acid solution, so that partial hydrolysis occurs. The resulting extract is, therefore, properly speaking, a solution of proteoses (with perhaps peptones and polypeptids) rather than of unbroken proteins. The therapeutic response appears to be adequate, and only one or two cases of anaphylactic reaction of a mild type have been reported in the course of the administration of tens of thousands of doses.

The detailed method of preparation of the nonspecific protein extracts (chiefly proteals) in my laboratory has been repeatedly published and has been communicated to the official Boards of Health in every State in the Union, of all large cities and to the Council of Pharmacy of the American Medical Association.

The resources of my laboratory were offered without reserve to the government throughout the war and are at the command of any hospital or institution, official or unofficial, where patients are under treatment to whom this line of medication might be beneficial.

I welcome also the cooperation of fellow practitioners everywhere, and my standing offer to supply proteals in any quantity entirely without remuneration for the treatment of charity cases in the hands of qualified practitioners anywhere in the world, is still open, and is taken advantage of. I am happy to say, by so many physicians that the resources of my small laboratory are constantly taxed to the utmost.

This laboratory is a department of the office in which I practise medicine; its prime object is experimental and to make the benefactions of nonspecific protein therapy available everywhere until such time as pharmaceutical houses qualified for the task, and hospitals and Boards of Health in general, take up the work of producing nonspecific proteins.

To avoid any possible misunderstanding, let me explain that my laboratory is not a commercial institution. Its methods are, however, open to full observation of any legitimate pharmaceutical houses, to several of whom, indeed, I have suggested the making of proteals after the formula used in my laboratory—explicitly specifying that no restrictions are or can be placed on the method; that it is not necessary to mention me in connection with it; and that under no circumstances would I consider or accept any commission, royalty, or other honorarium in connection with the matter.

I make these personal statements with great diffidence, and only to prevent any possible misunderstanding which might act prejudicially in retarding the acceptance of a method that has already stood the test of practical application at the hands of many hundreds of physicians, but which cannot hope to find its way to the great mass of the profession except by slow and gradual stages, involving months or years.

Having said so much, I am constrained to quote the opening paragraphs of a review of my book ("The Proteomorphic Theory and the New Medicine") which appeared in the number for May, 1921, of *The American Journal of Clinical Medicine*, because the reviewer explicitly calls attention to an aspect of the matter that has genuine significance:

> It is a well known fact that any new method of treatment, claiming to be successful in cancer or any other serious pathological condition, is compelled to run a gauntlet of scepticism, misrepresentation, and even worse. This is not fair either to the cause of science or to the suffering public, for, if a cure for cancer is ever found, any unnecessary delay in bringing it into general use by physicians will mean unnecessary suffering and death among cancer victims. Who will be responsible for those unnecessary deaths? Clearly those who, through bigotry, have put obstacles in the way of the prompt adoption of the new system of treatment. We doubt whether this phase of the matter is considered as often as it should be.
>
> This author claims to have discovered a new principle in physiology and to have successfully applied it in the treatment of several somewhat intractable diseases. If his system is based on a false foundation it will die without being kicked to death; but if it really is what he believes it to be, then we all have a responsibility in seeing that suffering humanity gets the benefit without unnecessary delay.
>
> The present reviewer has, for the past two years, been observing the results of the proteomorphic treatment whenever opportunity offered, more especially in cancer, rheumatism, and psoriasis. While the cases have been few in number, and while it is quite true that one swallow does not make an inebriate, the results have been so remarkable as to abundantly justify further observation and experiment.

I suggest that the reader cast his eye again over the first paragraph of the above quotation, and meditate for a few moments on its implications before proceeding to examine the matter that follows. As an aid to such meditations, I will merely point out that the statistical proof of the efficacy of protein treatment in ameliorating the condition of cancer sufferers was published in a medical journal of high standing as long ago as October, 1915. Since then more than half a million victims of

cancer have gone to their graves, in the United States alone, unsolaced by a treatment that might have been available for every one of them but for—

I permit the reader to finish the sentence out of the materials of his own meditation.

Let us now take up the trend of our story.

The Theory of the Protein Response.—The thoughtful physician will be sceptical, and properly sceptical, about the possibility of applying any single method to a wide range of maladies, unless he can be shown that there is a plausible physiological and pathological basis for such application. Let me, therefore, hasten to assure the reader that the new method fully meets these conditions. I stated some years ago, and I reiterate, that we have a clearer knowledge as to why and how nonspecific proteins elicit their response than we have as to the intimate nature of the action of most familiar drugs, including morphine, strychnine, and digitalis.

When any writer stresses "the incompetence of our knowledge" in this connection, his statement must be viewed as a personal expression, and his position may be likened to that of the British peer who, as reported by Lord Avebury, remarked as the two were walking home one night from the House of Parliament: "How strange it is that the moon changes its shape night by night. I suppose we shall never know the cause of this remarkable phenomenon."

Knowledge of the nature of the protein response is, indeed, incomplete in the sense that all knowledge of biological processes is incomplete. But in comparison with our knowledge of the intimate action of familiar alkaloids and of serums and vaccines, for example, our understanding of the protein response is adequate. The explanation is based on the assumption (supported by much evidence) that the blood corpuscles are the mechanisms directly concerned in the hydrolysis of any foreign protein that enters the blood stream. The stimulus to responsive activity on the part of the blood-forming mechanism given by any protein whatever is, in this view, direct and unequivocal. I have presented detailed evidence as to this in my earlier writings.

The physician who is interested in a full exposition of the subject may advantageously consult these publications. Here there is space only for the most condensed epitome, under a few suggestive headings. Let us lay the foundation by considering:

The Histological Evidence of the Protein Response.—Here we must discriminate sharply between the administration of bacterial proteins associated with bacterial toxins and the administration of therapeutic doses of relatively nontoxic proteins or protein products extracted from milk, egg albumin, animal tissues, or vegetable products, notably seeds. The former cause a more or less profound febrile reaction, accompanied by marked leucocytosis; the latter, administered in appropriate doses, cause no appreciable toxic symptoms, and the response of the blood-forming mechanisms is something quite different and altogether characteristic. In general terms, this may be described as a tendency toward normalization of the blood conditions.

Possibly the word "rejuvenation" would be more appropriate here than the word "normalization"; for there is one very notable and characteristic modification of the blood histology—namely, the increase of large monocytes—that makes the blood-picture of the patient under nonspecific protein treatment simulate that of childhood and adolescence. The observed fact of this increase of large monocytes under protein treatment (combined with the clinical observation of the coincident modification of neoplasms) led me to formulate the hypothesis that leucocytes of this type are particularly concerned with the early stages of hydrolysis of foreign protein molecules in the parenteral system. The well known fact that the large monocytes have relative preponderance in the blood of children during the period of growth (when, obviously, there is call for the handling of excess quantities of protein for the building up of tissues) is at least suggestively consonant with that hypothesis.

The other typical modifications of the blood under protein treatment, including increase of hemoglobin percentage, and normalization of the count of both red and white corpuscles in the aggregate, are features demonstrated by so large a number of cases in my personal experience, and in the experience of associated workers, as to be adequately established. The therapeutic bearing of these observations will be obvious to any clinician.

Nonspecific Proteins and Practical Medicine.—In the MEDICAL RECORD article of November 22, 1919, I gave a list of one hundred consecutive cases from my office records, thinking thereby to present a clearer picture than could otherwise be given in the same space of the various types of maladies that came within the range of nonspecific protein therapy. In a subsequent paper (December 20, 1919) these cases were grouped, for analysis of blood conditions, under the following headings: 15 cases of intestinal toxemia; 20 cases of neurasthenia; 18 cases of tuberculosis; 18 cases of dysthyroidism; 29 cases of disturbed metabolism.

The first four of these groups are self-explanatory. The fifth group brought together cases of great clinical diversity, including asthma, arthritis, anemic obesity, carcinoma, diabetes, psoriasis, and rheumatoid arthritis—all of them conditions which, in my opinion, are associated etiologically with protein toxemias.

That was the belief that led me to apply protein treatment to these widely divergent maladies. A study of blood conditions accompanied the clinical observation of every case. Characteristic modifications of the blood under treatment were associated, in the great majority of cases, with clinical modifications of gratifying character.

It would be worse than futile, in the space now at command, to attempt even a summary of results. Suffice it that the accumulated experience of the intervening months has served merely to support and accentuate the conclusions presented in the publications previously referred to. If I affirm now with dogmatic brevity that nonspecific protein therapy offers invaluable aid in the treatment of a large proportion of the cases of the maladies just mentioned, I am voicing no mere theoretical preconception, but an opinion based on personal observation of adequate series of cases, supported by the independent observations of several hundred phy-

sicians who have used protein antigens supplied from my laboratory.

With much confidence, then, I reaffirm the statement I have made again and again that nonspecific protein therapy offers the most comprehensive therapeutic measure known to present-day medicine. That the method should have come so far in six years is a testimonial to the receptivity of the profession; yet the fact that it has come no farther tells a story of conservatism that is regrettable even if not surprising.

The method is as simple as it is generally available. The practitioner who permits a case of anemia, of leukemia, of goitre, of tuberculosis, of cancer, of arthritis, of albuminurea, of glycosuria, of arteriosclerosis, of psoriasis, of asthma—naming only a few salient conditions—to pass through his hands without at least making the effort to give the benefits of nonspecific protein therapy, cannot be regarded as in touch with the trend of the times. That much at least may be said without challenge.

The Specific Element in Nonspecific Protein Therapy.—At the risk of seeming to propound a paradox that is subversive of much that has gone before—a paradox, however, that I shall endeavor to explain more in detail in another connection—permit me in conclusion to make this statement:

I have spoken all along of nonspecific protein therapy, and have not attempted to qualify the phrase, because the term has attained a certain meaning in current usage and I did not wish to create confusion. But I would have it recalled that in my original exposition of the subject I did not speak of *nonspecific* protein therapy but of *protein therapy* without qualification.

In the exposition of the Proteomorphic theory I have elaborated the conception that every type of protein has specific significance in its relations to the living organism. I have endeavored to elucidate the character of the general protein response, but I have never lost sight of the fact that there are specific features (as gauged, for example, by anaphylaxis) in connection with every protein used as an antigen, in addition to the general or nonspecific features.

Even in the present brief résumé I have intimated that there are at least quantitative differences between the responses evoked by, for example, egg protein, milk protein, serum protein, and various vegetable proteins.

Physicians familiar with details of my work will recall that one of the new therapeutic principles I have enunciated is that in dealing with cases of profoundly disturbed metabolism—for example, cancer—no single protein, even if administered for an indefinite period, can evoke a maximum response or produce optimum results. It is necessary from time to time to shift to a different protein—for example, from the protein of alfalfa seed to that of millet or clover or rape or hemp or cotton seed.

But it must be manifest that this implies specificity in connection with the response to each protein; not specificity in the sense in which we use the word in connection with pathogenic bacteria, and yet something analogous because implying that every protein has certain qualities that differentiate it from every other protein.

To elaborate this feature of the subject would obviously carry us far afield. Yet even a summary treatment of the subject of nonspecific protein therapy would be a very incomplete record of present knowledge were it to overlook the fact that the phrase "nonspecific" is used in a loose sense; that what we really mean when we use the phrase is—protein antigens dissociated from bacterial toxins; and that, in the final analysis, and with regard to the ordinary and accepted meaning of words, all protein therapy is specific therapy.

In the therapeutics of the future, bacterial toxins may have a place. Bacterial proteins dissociated from their toxins will probably have a place along with numberless other proteins of vegetable and animal origin. Ultimately we shall know which protein, bacterial, vegetable, or animal, will evoke the most satisfactory or desirable response when this or that pathological condition of the organism obtains.

Then we shall be practising scientific protein therapy of a new type of specificity, which will almost surely supplant the old specific serum therapy and vaccine therapy.

Pending the acquisition of the new knowledge that will bring us to this culminating phase of Protein Therapy, we have at the moment, particularly in the vegetable proteins, materials for the application of a method to which the term Nonspecific Protein Therapy may justifiably be applied to distinguish it from Serum Therapy and Vaccine Therapy; and I repeat that these nonbacterial protein antigens constitute even to-day the most comprehensive and under many conditions the most satisfactory agency available for the practical physician in combating a wide range of metabolic disturbances, including the major part of the so-called degenerative diseases that are responsible for perhaps three deaths out of five in the adult population.

104 EAST 40TH STREET.

PRESENT OPINION ON INTRASPINAL THERAPY IN NEUROSYPHILIS.

BY EUGENE N. BOUDREAU, M.D.,

SYRACUSE, N. Y.

CHIEF OF NEUROPSYCHIATRIC CLINIC, SYRACUSE FREE DISPENSARY; INSTRUCTOR IN NEUROANATOMY AND ASSISTANT PROFESSOR IN NEUROPSYCHIATRY, SYRACUSE UNIVERSITY MEDICAL SCHOOL.

IT is the purpose of this paper to try to remove some difficulties, and to help to clear thinking in the problem of treatment in neurosyphilis. The literature on the subject is abundant, conflicting, and confusing and leaves one in doubt. For the busy general practitioner who is beset continually with the need of gaining the best opinion concerning the problems in many fields, this situation is lamentable. With the hope of getting into convenient space and form the essential facts, this abundant literature was gone over and sifted, and only that which was most convincing selected. It was also a concern of the writer to deal impartially, therefore the best was sought from centers as far removed from one another as possible so as to minimize the element of personal influence among the observers. Authors are quoted verbatim in many instances where it has seemed best.

Now, in order first to gain a perspective of the

whole situation, let me give, briefly, the essential points which seem to me important as they appear crystallized from this vast material:

All agree that the central nervous system is invaded *early after infection* by the *Spirocheta pallida*. Also that in some cases the nervous system spontaneously takes care of itself, while in others the offending elements become harbored and resist elimination sturdily or seemingly become dormant and remain there for long periods—five, ten, or twenty years. It is consequently essential to subject this part of the organism to searching inquiry before it is considered free from danger. Most observers likewise agree that arsenic as salvarsan, neosalvarsan, arsphenamine or neoarsphenamine, given intravenously in the accepted way, together with courses of mercury and the iodides, is the logical first procedure. If the nervous system then is proven by laboratory and clinical scrutiny to be intact, all is well. However, when the proper amount of energy with intravenous treatment has been displayed and the nervous system shows itself yet to be not free from attack, then a wide divergence of opinion arises as to the best method of further procedure. This disagreement in opinions revolves largely about the question of the permeability of the blood vessels and choroid plexus to compounds of complex molecular structure like arsphenamine. Therefore, arise the questions: Does intensive treatment by intravenous injection produce all the possible desired results? Likewise does intravenous treatment with spinal drainage produce these results? (Spinal drainage is supposed by some to increase the permeability of the choroid plexus.) Or is it necessary for the spirocheticidal substance to be introduced into the cerebrospinal fluid by way of the spinal canal. Intraventricular introduction is objectionable because quite impracticable. It is pretty well agreed that mercurialized serum is a less desirable and more potentially injurious substance than salvarsanized serum.

Furthermore, I believe it will help to clarify much that follows if we consider briefly the known and accepted facts regarding the physiology of the cerebrospinal fluid. It is accepted that this fluid is produced only above the aqueduct of Sylvius, probably by the choroid plexus; likewise that it is slowly formed and gradually absorbed but the rate of formation and absorption, under normal conditions, is unknown. Physiologists also agree that this fluid has a circulation; it is believed, though not absolutely proven, that this circulation is from the ventricles to the subcerebellar cisterna, then to the cerebral and spinal subarachnoid spaces. In the spinal subarachnoid the circulation is downward posteriorly and upward anteriorly, the circulation is least complete in the lower spinal regions. It is known that the choroid plexus is not permeable under normal conditions.

It is believed by Halliburton[1] and some others that the cerebrospinal fluid comes into close contact with the cells of the nervous system by means of the perineuronal spaces and that it has the function here of lymph in other tissues, that is, it maintains osmotic pressure, nourishes the cells, and carries away waste.

It would not be possible within the limits of this article to discuss in detail conditions in the pathology of central nervous syphilis which would be related to the problem of intraspinal therapy. However, I believe it will be valuable to review briefly some of the changes brought about by syphilis in this system.

According to Nonne these pathological changes may be grouped under three great divisions, that is: (1) Syphilitic new growth. (2) Chronic hyperplastic inflammation. (3) Disease of the blood vessels.

The favorite locations of syphilitic new growths or gummata are in the dura, upon the convexity or at the base, but more often at the base where small tumors develop in the neighborhood of arterial trunks. Gummata sometimes appear in the cortex of the brain, most often in the region of the central convolution.

They also occur in proximity to the large ganglia, optic thalamus, lenticular nucleus, etc. With the gummata there is usually an accompanying meningitis. Gummatous tumors begin their growth in the meninges and connective tissues, and have no relationship to the nerve tissue, except in a secondary manner.

Syphilitic meningitis occurs in all three coverings but it most frequently starts in the pia, especially of the base. Virchow believed simple meningitis was a doubtful condition. Oppenheim on the other hand thinks it is not uncommon. The favored location of the meningitis at the base is in the interpeduncular space and about the optic chiasm.

As regards the arteries, it is the generally accepted view now that the primary inflammatory process is in the vasa vasorum and the perivascular or Virchow-Robin spaces, and from here spreads to the endothelium, which proliferates and gradually obliterates the vascular lumen. In the veins, the walls are involved in various ways, the result being obliteration of the lumen. The results of syphilitic disease of the blood vessels are not diagnostic, for they are the consequences of diminished or suspended nutrition to an area. Nonne says also that besides the three forms of nervous syphilis above mentioned, there is in addition a degenerative process of varied type "to which, for clinical reasons, syphilis must be regarded as standing in causative relationship," that is, a primary parenchymatous degeneration.

Barrett and Danvers have also described an acute inflammatory process which they designated "disseminated syphilitic encephalitis."

The same general processes occur in syphilis of the spinal cord, clinical manifestations depending upon the type of the pathology and its location.

It will be seen that in the first two types of process, the meninges are primarily involved and in the last a part of the initial process is outside of the vessel in the perivascular spaces. The perivascular spaces are probably in direct communication with the subarachnoid space, as is evidenced by the appearance of lymphoid and polynuclear cells in the spinal fluid in inflammatory conditions of the meninges, and also because the vessels carry pia into the cortex with them as they dip down within it. For these reasons it would seem essential, in most cases, that our therapeutic agent reach the meninges, therefore the importance of the question of the permeability of the blood vessels to our agent.

Let me submit now the material from which the above condensations have been made.

In February, 1919, P. Fildes[2] of the Royal Naval Hospital, Haslar, England, reported the following conclusions from a series of 624 unselected cases of syphilis in all stages of the disease:

1. Eighteen per cent. had 10 cells or over per c.mm. in the cerebrospinal fluid.
2. Eighty per cent. of these showed no clinical signs of the nervous disease, altnough the spinal fluid showed as high as 1,000 cells per c.mm.
3. Some cases of pleocytosis occur soon after infection, and before the Wassermann reaction in the serum becomes positive.
4. In cases having no active signs of syphilis over 6 months from infection 35 per cent. had 10 cells or over per c.mm. in the cerebrospinal fluid.
5. That the changes in the cerebrospinal fluid were due to syphilitic disease of the central nervous system was demonstrated by the increase of cells mostly lymphocytes; by the presence of a positive Wassermann reaction; and by the fact that treponema pallida was demonstrated in the cerebrospinal fluid.
6. A negative Wassermann reaction in the serum does not in every instance exclude the possibility of active syphilitic disease in the central nervous system.
7. Previous treatment has had no effect on the number or the severity of the abnormalities in our series.
8. In nearly all cases intravenous treatment has had a beneficial effect, but in a few cases the pathological processes in the central nervous system have not been checked even by repeated courses of this treatment.

Examination of the cerebrospinal fluid is indicated in every case of syphilis. Swift in December, 1917, said[1]:

To neglect either clinical or laboratory signs is not in accord with modern tendency in clinical medicine. To disregard the laboratory picture of disease is at least reactionary. In syphilis, laboratory evidences of disease are of paramount importance and changes give us a valuable measure of the efficacy of our therapeutic measures. It is always well to separate, as far as possible, the symptoms that are the result of active disease from those the result of scars. The elimination of active syphilitic foci and the arrest of progressive degeneration are objects of our therapy.

In a large majority of the tabetics in whom the Wassermann reaction has been rendered negative in blood and spinal fluid there has been no progressive downward course as determined by periodic clinical examination. On the other hand in those cases (of tabetics) in whom it was impossible to influence appreciably the abnormal laboratory findings the disease was often progressive. These often showed a paretic gold curve. In paresis, increase in number of remissions and their length is all that can be expected (from intraspinal treatment).

We must differentiate sharply between concentrations of arsenic that are injurious and the injection of a serum reenforced by a fraction of a milligram of salvarsan, which is practically never followed by any bladder disturbance. Although the serum contains only minute quantities of salvarsan, it has been established as spirocheticidal by several workers. I have shown that injection of normal serum decreases the Wassermann and cells. In some cases that were stationary under this treatment, there was further improvement when "salvarsanized serum" was used. Hence we have two favorable factors at work which do no injury to delicate central nervous tissues.

While there has been an occasional report of finding of arsenic in spinal fluid after intravenous administration, the majority of investigations show negative results. We are, therefore, justified in concluding that the choroid plexus and the capillaries are usually effective barriers to the passage of arsenic into cerebrospinal fluid.

Blackfan and Dandy showed that after intraspinous injection of finely divided carbon there was a rapid distribution of the particles throughout the subarachnoid space.

Not infrequently intraspinous injections are not advised in all cases because general treatment is alone sufficient.

Sachs[4] opposes the use of intraspinal treatment and says:

Let me state briefly why we pinned our faith to the intravenous use of salvarsan, neosalvarsan or arsphenamine and why we are ready to reject the more dangerous intraspinous method of treatment.

If the intraspinal methods were to be adopted and heralded as the only effective treatment of syphilis of central nervous system, the greater harm would be done, because the intravenous method would not then be energetically pursued by the hundreds of physicians who have become skillful in its use and which brings results comparable with those obtained in the treatment of early specific lesions in other organs. If there is the slightest suspicion that syphilis has invaded the nervous system, let doctors give intravenous treatment and give it to the extent that we have found safe. In general paresis and tabes the chief lesions are deep within the substance of the brain far removed from the cerebrospinal fluid. It is for that reason almost impossible to bring the spirocheticidal remedy into immediate contact with the foci of disease unless these remedies can be introduced through the blood stream. It is only in the earliest stages of tabes that the disease, as we have long known, involves the meninges and spinal ganglia; later on it sets up marked changes in the spinal tissue and these secondary changes are entirely beyond the reach of the cerebrospinal fluid. In the remaining processes . . . we would suppose that spirocheticidal substances introduced into the cerebrospinal fluid might have an active therapeutic effect if such substances could course freely in the cerebrospinal fluid and if it could be shown that they were retained in the fluid any satisfactory period of time. (He also refers to his demonstration, with assistance of Professor Benedict, in 1914, that salvarsan introduced in the usual quantities into blood current appeared in the cerebrospinal fluid in appreciable quantities.) It has also been shown that the cerebrospinal fluid circulates imperfectly and that there is little absorption of this fluid by the cortical spinal cells. (He gives no reference.)

Stoner[5] of Cleveland in February, 1917, discusses his experience in seventy-two cases who had 252 treatments by the Swift-Ellis-Ogilvie* method. The cases included all types of neurosyphilitics. Of patients made clinically well two had had intensive treatment previously and were not completely relieved, but intraspinous treatment gave complete relief. Seven cases getting clinically well were treated simultaneously, intravenous alternating with intraspinous. Experience shows that intraspinous treatment cannot supersede the general treatment, but must be used as an adjunct to it. It is not his belief that intraspinous treatment is indicated in early neurosyphilis unless general treatment has failed. As long as involvement is meningeal in character, because of blood supply we have a right to believe general treatment is sufficient. The proof however of sufficient treatment should be negative cerebrospinal fluid findings. No patient with early syphilis should be dismissed on a blood negative to the Wassermann reaction. A positive spinal fluid then is indication for intraspinal treatment, even though clinical signs are absent.

It is striking how much relief one intraspinal treatment will give in an early neurosyphilitic not responding to general treatment. The tabetics, if intensely treated, become less ataxic, lose lan-

*The use of salvarsanized or arsphenamized serum intraspinally with the addition of a fraction of a milligram of salvarsan or arsphenamine directly to it.

cinating pain, and crises disappear. The relief is so great, they solicit further treatment. Clinical improvement does not always parallel laboratory improvement, however, nor is it always in the negative laboratory cases that the greatest clinical improvement is seen.

"Syphilis, like tuberculosis, is everywhere—it is present often with no history of infection. A positive Wassermann or lumbar puncture is the only manifestation. A neurosyphilitic involvement rarely gives negative lumbar puncture findings."

Drs. Goodwin and Scott of St. Luke's Hospital, New York, in July, 1919, reported the results in 214 treatments on twenty-one cases.[6] They found that lost knee-jerks or sluggish pupils are not changed. There is frequent improvement in ataxia and cases almost uniformly show improvement in weight from sixteen to thirty-one pounds. The most gratifying results from the treatment have been shown by its effect on the subjective symptoms. In spite of the fact that the intraspinal treatments often cause severe reactions, they found these patients more anxious to continue treatments than any other class. Also they were struck by the fact that in most cases there was a very marked and sustained diminution in the amount of discomfort from which they suffered before the institution of treatment. In almost every one of the cases recorded there was relief to a great extent from pain and frequent improvement in bladder function. Of two cases of spastic type of tabes one recovered from spasticity and reflexes returned, the other showed moderate improvement.

Dr. Fordyce,[7] whose wide experience in the treatment of syphilis is well known and whose ability as a clinician can be little questioned, though by some considered an enthusiast, reports his latest studies and convictions in July, 1919. He says:

> The pathological studies of Warthin in visceral syphilis which show that spirochetæ may be harbored for years with slight or no reactive phenomena support the theory of the persistence of the infection *in loco*. It does not require a great tax on our reason to suppose that the spirochetæ behave much the same way in all organs which they invade. We may, therefore, transfer our experiment to the central nervous system. With its more specialized centers and tracts spirochetal attacks may cause marked subjective or objective symptoms and signs like headache, delirium or paralysis of most varied types. On the other hand an individual so infected may remain free from all symptoms for years until some important center or tract is compromised. In some of these cases, however, where slight character defects are the only deviation from the normal the physical signs are practically nil, the blood and spinal fluid reveal the formula which speaks for paresis. "Paresis sine paresi" may exist for years without the well-known stigmata and in my opinion is not a sudden invasion leading to the patient's death in two or three years.
>
> If we admit, as I think we must, that neurosyphilis, like its prototype in other organs, may have long periods of latency, it is not difficult to believe that the spirochetæ gained entrance to the nervous system in their period of greatest dissemination, *i.e.* the florid stage. Since attention has been directed to early neurosyphilis, careful clinical examination has uncovered a large number of cases. More definite knowledge has been acquired by spinal fluid examination at this time.
>
> Assuming the early implication of the nervous system to be correct the vast importance to the individual of early recognition of such an involvement is self-evident. The Wassermann reaction is our guide and as long as the test continues positive the future of the patient is menaced. A positive Wassermann reaction which remains for years uninfluenced by intensive treatment or which returns after treatment is discontinued is not infrequently caused by neurosyphilis. The blood (reaction) becomes negative for a time, but it is reinfected by the spinal fluid.
>
> In order to make my position quite clear regarding the indication for intraspinal therapy, I desire to emphasize the statement often made that the method is of value in certain types of neurosyphilis which *fail* to respond to treatment by other channels and in which the spinal fluid reveals an *active* syphilitic lesion. If a patient, after intensive treatment with salvarsan, mercury and potassium iodide, shows little or no improvement in his symptoms, blood or fluid reactions, some other method of therapeutic attack would be clearly indicated. Rapid and decided clinical and serologic improvement following the introduction of a new factor, even though the original procedure might be continued would strongly suggest to a mind free from prejudice that the new factor was responsible for that change.
>
> I have demonstrated again and again in my laboratory the persistence of positive phases in the spinal fluid in patients treated in the most intensive manner by the orthodox methods over long periods with little or no change except in the cell count and slight clinical improvement. Intraspinal therapy has been followed by persistent negative phases and clinical improvement or cure. I am, therefore, becoming more and more convinced of its value and believe the failure of others to obtain like results to be largely dependent upon imperfect technique and early discouragement because of slow results.

(The article also describes in graphic form twenty-six cases of the various types of neurosyphilis in early stages which were benefited or cured as regards clinical and laboratory manifestations.)

In another article Dr. Fordyce says "It would be hard to convince most of my patients on theoretical grounds that they had derived no benefits from the treatment."

Dr. Fordyce is so convinced of the possibility of limiting syphilis by treatment with present day methods well carried out that I have heard him say "Syphilis can be as thoroughly controlled as typhoid fever."

Other methods of treatment by means of the cerebrospinal fluid have been tried and advocated. One, the use of mercurialized serum, advocated by Byrnes, has been found by Haller[8] of Boston and Neyman[9] and Brush of Baltimore, though having certain advantages in preparation, to produce more severe reactions than salvarsanized serum and to have greater potential danger.

Dercum[10] of Philadelphia, in an article published in December, 1919, advocated complete spinal drainage once in ten days to two weeks. He bases his belief in this method on the theory that the beneficial results obtained in the Swift-Ellis treatment are from the necessary spinal drainage practiced in it; also on the theoretical proposition that the drainage results in an increased pressure in the blood vessels of the nervous system producing a hyperemia, "a parallel to the Bier method in surgery"; and a replacement of old fluid by new which produces a lavage of the subdural space. His explanation of the basis for the treatment rests upon a physiology of the cerebrospinal fluid largely of his own conception and at variance, I found, with many of the ideas of such men as Halliburton, Weed, and Mestrezat. These latter base their ideas or hypotheses upon experimental evidence. Dercum

lays no claim to experimental experience but bases his reasons upon analogy from known facts regarding other tissues and upon purely theoretical conceptions.

It is well here to call attention to the fact that spinal drainage results frequently in great pain, which does not often occur when the fluid withdrawn is replaced by serum. I might say that I believe Drs. Fordyce and Cornwall have been unable to reproduce the results claimed for spinal drainage whether or not salvarsan was previously given intravenously.

It seems hardly necessary to speak of the objections to intraventricular injections, especially in incipient neurosyphilis.

Now let us consider briefly what conclusions we can safely accept. It would appear that they are these.

1. The central nervous system is early invaded by the *Treponema pallidum*, and without necessarily giving clinical signs.

2. Vigorous intravenous salvarsan treatment associated with mercury and the iodides removes the danger in a larger number of cases. This must be confirmed by negative findings in the cerebrospinal fluid.

3. Certain cases do not respond to this treatment alone.

4. For these cases the best treatment so far devised, but not ideal, is by the Swift-Ellis-Ogilvie method because various observers agree that clinical evidence shows it to be beneficial and the laboratory evidence is that in all but potential paretics the signs become negative if thoroughly carried out, and because both avenues of approach are employed.

5. That the method of Byrnes (mercurialized serum) is more dangerous and produces severe reactions.

6. That the drainage method of Dercum is not without danger, is extremely painful, and the results obtained by observers are not in agreement.

305 PHYSICIANS' BUILDING

THE USE OF THICK CEREAL MIXTURES IN DIFFICULT FEEDING CASES.*

BY HENRY DWIGHT CHAPIN, M.D.,
NEW YORK

DURING the past few years a number of observers have reported striking results from the use of thick cereals in a number of abnormal conditions that may occur during early infancy. Dr. Sauer[1] got good results in various types of neurotic vomiting and in pyloric stenosis. Dr. Helmholz also obtained relief in cases of pyelospasm. Dr. Mixsell,[2] in two series of cases, succeeded in checking malnutrition in infants who could not be made to gain on ordinary feedings. Dr. L. Porter[3] obtained good results from this feeding in idiopathic vomiting and in certain cases of wasting by restoring nutritional balance.

The cases here reported consisted of infants who were suffering from obstinate indigestion which resulted in distinct malnutrition and pointed to the hopeless marasmus that finally resists all aid.

Twenty of the infants were inmates of the Alice Chapin Adoption Nursery. This nursery accepts abandoned infants and prepares them for adoption. Some of these infants are exceedingly difficult to manage. Most of them are illegitimate and have been removed from the mother immediately or shortly after birth. Various bottle feedings are then tried and, after a few weeks shifting about, the infant is received at the nursery with apthous patches in the mouth, excoriated buttocks, and all the evidences of faulty digestion. In passing, it may be remarked that only a few weeks at the breast at the very beginning of life would make the handling of such cases much easier, as a fair nutritional start is very essential to the welfare of these infants. Some of the infants cannot digest or assimilate normal feedings for their age. Accordingly, weak mixtures must be given to suit their digestion. Loss of weight follows, and the digestive power grows still weaker. This vicious circle, unless relieved, soon ends in death. Any form of food that will check this wasting until the infant has time to adjust itself to a normal food is worthy of trial. As many of our nursery infants do not increase in weight, and frequently lose on a formula normal to the age, it was determined to try the cereal feedings in selected cases.

Three mixtures were employed, prepared as follows:

I.

Boil one-half hour { Remove top 4 oz. from 1 qt. milk. / Skim milk, 11 oz. / Water, 7 oz. / Farina, 3 level tablespoonsful / Add granulated sugar, 1 level tablespoonful

Feed 3 oz. every 4 hours, and water every 4 hours, alternating.

II.

Boil one-half hour { Remove top 4 oz. from 1 qt. of milk. / Skim milk, 15 oz. / Water, 6 oz. / Farina, 3 level tablespoonsful / Add granulated sugar, 1 level tablespoonful.

Feed 3½ oz. every 4 hours, and water every four hours, alternating.

*Read on June 2, 1921, before the American Pediatric Society at Swampscott, Mass. (See page 568.)

III

Remove top 4 oz. from 1 qt. of milk

Boil one-half hour { Skim milk, 28 oz.
Water, 9 oz.
Farina, 4½ level tablespoonsful.

Add granulated sugar, 1 level tablespoonful, and malt sugar, 1 level tablespoonful

Feed 4 to 6 oz. every 4 hours, and water every 4 hours, alternating.

Most of the cases thus fed were vomiting as well as losing weight when the paste was started. Some of the infants took the cereal best through a nipple. In these cases a large hole was made in the nipple and two level tablespoonsful of farina was used for formulas I and II, and two and a half tablespoonsful for formula III. When vomiting was an important feature, the thicker cereal did better, and they were always first tried with a spoon. The persistent vomiting in some of the cases was largely responsible for the loss of weight. The use of water seemed to be helpful in aiding to increase the bulk of tissue. We could usually get the very little babies to take from 4 to 5 ounces in the twenty-four hours, and the older ones 5 or 6 ounces. The water was given through a nipple, the same as ordinary milk feeding, and some infants took it with avidity, while others had to be coaxed. Whole milk was usually substituted for skim milk after the vomiting stopped. Several very large, yellow, fairly homogeneous stools were usually noted.

The effects of this feeding were occasionally uncertain, usually good, and sometimes remarkable. The babies seemed to like the taste afforded by the cane sugar, and the gelatinized starch appeared to prevent a laxative or fermentative effect from the sugar. Since starch is a complex carbohydrate, it is slowly converted and thus affords less opportunity for fermentation. The gelatinized starch also carries a high protein content for the age into the digestive tract in colloidal form. The mechanical splitting up of the coagulated protein and the ballast to the bowel afforded by mere bulk also seems to have a stabilizing influence. As starches and sugars are carriers of energized carbon and water, the gain in tissue may thus be explained. A low osmotic pressure of the starchy mass and a lessened stimulus of the food tends to inhibit glandular secretion. Daniels[4] believes that growth is stimulated in young infants by the addition of wheat embryo to food, supposed to be induced by an antineurotic vitamine.

The following table shows the age of the infants, the weight when the food was started, the weight when it was discontinued and the duration of the trial.

R. F.	3 weeks	5 lbs., 12 oz..	gained	2 lbs., 2 oz.	in	5 weeks
K. W.	7 weeks	7 lbs., 5 oz..	gained	3 oz.	in	4 days
W. P.	2 weeks	7 lbs., 2 oz..	gained	14 oz.	in	2 weeks
W. S.	7 weeks	6 lbs., 14 oz..	lost	3 oz.	in	5 days
R. A.	10 months	12 lbs., 9 oz..	gained	2 lbs., 10 oz.	in	3 weeks

Peter S., 5 weeks, was admitted to the nursery on May 6 weighing 5 lbs. 15½ oz. He soon developed a diarrhea and was put on protein milk. The bowels gradually became normal, but he began to lose weight—on May 11 showing a loss of 2 ounces. On May 12 he was started on thick cereal and on May 20 he weighed 6 lbs. 13½ oz. We have had this experience in several other cases.

In two infants treated at the Babies' Wards at the Post-Graduate Hospital, an examination of the stools was made in the laboratory by Miss Hilda M. Croll to determine the carbohydrate utilization during the thick cereal feeding. One baby of five months gained 2 ounces, and one of eight months lost 2 ounces after three days of thick cereal feeding. In both cases the carbohydrate intake was weighed for the three consecutive days, and during this time all the stools were collected for examination. The results are shown in the following table:

Carbohydrate Intake and Carbohydrate Output in the Stools.

Patient	Age Mos.	Period Days	CHO Intake Grams	No. of Stools	Wt. of Moist Stools	Reaction to Litmus	Reducing Sugar Grams	Non-Red. Sugar Grams	Total CHO Grams	Percentage of CHO Utilized
A. S.	8	3	187	5	92	Acid	0.296	0	1.55	99.3
P. C.	5	3	101	9	102	Acid	0.461	0	2.39	97.6

The percentage utilization of the carbohydrate in this diet, consisting largely of farina and cane sugar, was 99.3 per cent. for one infant, and 97.6 per cent. for the second. Myers and Rose[5] found utilizations by adults of 98 to 99.8 per cent. of the carbohydrate of ordinary mixed diets. Pease and Rose[6] found utilizations by children of 97.2 to 99.5 per cent. of the carbohydrate of mixed diets. It is thus seen that in the two cases here examined the carbohydrate was utilized by these infants practically as well as the carbohydrate in an ordinary diet was utilized by adults and children.

The following was the method used by Miss Croll in determination of the carbohydrate in the stools:

The combined stools for the period are extracted by a thorough mixing of cold water and bringing the mixture to boiling in a flask. A small portion of this water extract is saturated with dry picric acid and 3 c.c. portions are heated with 1 c.c. 22 per cent. sodium carbonate in a test tube, in a boiling water bath for 20 minutes. After dilution, the red-brown color produced by the reduction of sodium picrate to sodium picramate is compared in a colorimeter with a standard glucose solution similarly treated. The soluble reducing sugar is thus determined in terms of glucose. Nonreducing soluble sugar is determined by heating 3 c.c. of the extract with picric acid alone for 10 minutes, and then heating with the sodium carbonate. The picric acid inverts any cane sugar to reducing sugar.

The original mixture of the stools with water is boiled with approximately .06 normal hydrochloric acid for 2 hours, cooled and neutralized, and a portion of the filtrate is saturated with dry picric acid; 1 to 3 c.c. are heated with sodium carbonate as for soluble reducing sugar. The total carbonate of the stool is changed to reducing sugar by this acid hydrolysis and is expressed as glucose.*

From a study of the cases here reported, we can confirm the view that thick cereal mixtures form a valuable resource in certain cases of persistent vomiting and will check wasting in some infants

*The procedure for this method is a modification of that used to determine the carbohydrate in vegetables and fruits, as described in a paper by Myers and Croll to appear in the *Journal of Biological Chemistry* for May, 1921.

that fail to hold their weight on ordinary food formulas.

51 WEST FIFTY-FIRST STREET.

THE HEMORRHAGES IN THE NEW-BORN.

BY J. R. LOSEE, M.D.

NEW YORK.

PATHOLOGIST TO THE NEW YORK LYING-IN HOSPITAL.

THE following remarks refer entirely to the more serious hemorrhages in the new-born and no mention will be made of the hemorrhages associated with asphyxia. Of those cases where the life of the infant is often in danger, we have for our consideration the so-called idiopathic hemorrhage and hemorrhage due to injury. These babies are not suffering from hemophilia, but their condition is peculiar to the first few days of life, and whereas in the spontaneous variety we are ignorant of the cause I believe that the hemorrhage persists because the hematopoietic system is not complete when born and their blood does not contain the necessary substances to promote clotting. This condition is present in both males and females and several have been seen from one to two years after birth without any history of a recurrence. In a large series of autopsies I have observed that the more premature the infant the greater the danger of hemorrhage. I am convinced after the clinical observation of many of these cases in the past few years that regardless of the cause the treatment is the same for both types.

On account of the difficulty in obtaining a sufficient quantity of blood from an infant it is impossible to carry out the more accurate methods for determining the coagulation time, the prothrombin time and other investigations necessary for a complete study of the fluid. Observers have reported both a prolonged coagulation time and bleeding time in some cases, in others the same observers have found a prolonged bleeding time and a normal coagulation time, and there is a third type of case where neither the coagulation time nor the bleeding time was increased. Hurwitz[1] has placed this disease in that group which shows lack of prothrombin, yet we have seen cases manifest typical symptoms without a delayed coagulation time. The prothrombin time in three cases that returned after one year was normal. It was not estimated during the course of the disease. Rodda[2] has reported two cases with both a delayed coagulation time and bleeding time that developed definite symptoms of hemorrhagic disease and two others with a delayed coagulation time and a normal bleeding time that showed no signs of it. It is apparent, therefore, that these cases do not all lack the same element in the blood and it is quite impossible to classify them on that basis.

Hemorrhage is the chief symptom observed. It may be mild, moderate and occasionally the initial bleeding is severe enough to endanger life. The bleeding may occur in any tissue, but it is most frequently observed in the subcutaneous tissues, the gastrointestinal tract, from the umbilicus and in the central nervous system. It has been noticed that after an extensive hemorrhage in one system a very slight or no hemorrhage is found in the others. These symptoms generally occur before the fifth day and they are sometimes associated with fever, absence of nursing and the general appearance of the infant is suggestive that it is not doing well. In some the entire subcutaneous tissues of the back are infiltrated with blood, in others there is an extensive hemorrhage beneath the dura mater, in others nearly all the blood in the infant's body is in a cephalohematoma and I have seen cases of gastrointestinal hemorrhage where a complete blood cast of the small intestine was observed at autopsy.

Inasmuch as this is a constitutional disease there is little advantage gained and considerable time wasted by applying local measures, even in those cases where it is possible to do so by reason of an external bleeding point, and, in spite of the numerous articles on the value of whole blood therapy, the majority of these cases continue to be treated with horse serum, thromboplastin, and calcium. It has been shown by Hurwitz[1] that old serum retards rather than hastens the clotting of blood both in normal animals and in those suffering from hemorrhagic disease. He also attributes little value to the use of fresh serum in this condition, and says after carefully controlled experiments that it has little effect on the coagulability of the blood. On the contrary our experience at the New York Lying-In Hospital has shown very good results with fresh normal human serum ever since it was introduced by Dr. J. E. Welch ten years ago. There are certain cases in which even serum or whole blood in large amounts subcutaneously will not control the hemorrhage and in these we must resort to whole blood intravenously. With this method we not only supply the therapeutic agent necessary to check the bleeding in any part of the body, but also overcome the acute anemia which is threatening life. Even after introducing blood directly into the circulation of these babies I have seen one in a series of sixteen cases recur after twenty-four hours. In this case we were dealing with a type which not only did not have the substances to produce clotting but possibly had sufficient anti-clotting substance in its blood to neutralize that introduced, or it may be that in the cases which do well the introduction of blood stimulates the production of the clotting substances, and in those in which bleeding recurs it does not produce such stimulation. It is our routine at the hospital to treat these cases early with fresh normal human serum or whole blood subcutaneously, but if the hemorrhage is not controlled by this method transfusion is performed and is followed by subcutaneous injections of serum for two or three days in the endeavor to avoid a recurrence. If the condition should recur and life be endangered another transfusion from a different donor is indicated. In those cases where the initial symptom is a profuse hemorrhage and the general condition of the patient is grave or if the case has been admitted

after bleeding sometimes at home radical treatment is at once instituted.

In the consideration of blood transfusion in these cases the question is repeatedly asked if it is necessary to make the compatibility tests on the infant. The presence of isoagglutinins in the serum and receptors in the red corpuscles of the infant have been very thoroughly observed by Happ.[3] He has concluded after making 67 tests on 49 infants, from one to twenty-one days old, that at birth the group is established in very few instances; that the serum of a newly born infant may contain no agglutinins and his corpuscles be inagglutinable; that the corpuscles become agglutinable before agglutinin is present in the serum; that in only 7 of the 49 infants tested was agglutinin present in the serum, though the corpuscles were agglutinated in 32 cases, and that it was possible to place only 8 of the 49 cases tested into a definite group. From his observations he says that he has not seen the serum give up an agglutinin or cells give up receptors which have once been acquired, and he does not believe that this occurs. He says that it is possible for an infant to acquire further agglutinins in his corpuscles and serum as he grows older, which places him in a different group from the one he apparently belonged to in the first few days of life. In twenty-three cases the grouping of the mother was determined simultaneously with that of the infant and on account of the difference between the agglutination reactions of the mother and child he concluded that it was not a safe practice to transfuse the infant from its mother without making the preliminary test.

I have been interested for some time in the demonstration of agglutinin and receptors in the blood of babies from one to ten days old because it has been in this type of case that I have found its practical application most valuable. The Moss method was followed in the same way as we use it for adults and the sera of one hundred newborns were examined. Of this number 32 showed the presence of agglutinins for II or III cells or for both. Six contained agglutinins for II cells, 12 for III cells, and 14 had agglutinins for both. Therefore, according to Happ, fourteen of these cases could be permanently classified as belonging to type IV, but inasmuch as the other two classes may develop agglutinins later for either III or II cells respectively, it was impossible to place them in a definite group. The corpuscles of 134 babies were examined for the presence of receptors and 15 contained receptors for agglutinins in serum II, 50 had receptors for the agglutinins in serum III, and one held receptors for both. It was possible to place only one in a definite group from this series of examinations on account of the possibility of the other 65 forming receptors for III and II agglutinins. It is true, however, that only one or two of this number would do this on account of the low percentage of cases in type I. I concluded, therefore, that, inasmuch as 32 per cent. of one series contained agglutinins and 50 per cent. of another series contained cell receptors, it was advisable always to make our preliminary compatibility tests regardless of the fact that many of these agglutinins are weak and would be diluted somewhat in the process of transfusion.

Both modified and unmodified blood have been used in this series of cases with equally good results. The blood was injected into one of the superficial veins in the cubital fossa of the arm after cutting down and this was accomplished even after cases had been almost completely exsanguinated. I am well aware that the longitudinal sinus route is the most popular at the present time for all varieties of intravenous therapy, but I am certain that it is not without its dangers in a definite proportion of cases. I have been successful in placing the blood beneath the dura on more than one occasion and have observed others supposed to be proficient in the art do likewise. The final results of such a procedure will not be apparent until early childhood. From 40 to 120 c.c. of blood have been injected, depending upon whether it is done for the therapeutic effect or whether we are also treating the anemia produced by the loss of blood. In cases where external bleeding is present, as from the cord or skin, the result is very apparent, for in most cases the bleeding stopped before the transfusion was completed. A reaction, if present, in these cases is manifested by a slight rise in temperature from one-half to two hours afterward, which promptly subsides and the general condition is noticeably improved.

The following is a brief clinical history of sixteen cases treated by blood transfusion. Eight of these had been treated with normal human serum without any result and in one the hemorrhage recurred after blood transfusion. There are seven cases of subcutaneous hemorrhage, three of cerebral hemorrhage following operative delivery, three of hemorrhage from the ubilicus, two with gastrointestinal hemorrhage, and one from the wound following circumcision. Two of the babies with cerebral hemorrhage have been reported by their attending physician to be well one year after birth. No neurological examination has been made on these cases however.

Baby G. Delivered by high forceps and the following day a bilateral cephalohematoma was observed in the occipital region. During the following forty-eight hours numerous subcutaneous hemorrhages were observed over the back and face and there were symptoms of cerebral irritation. Two hundred and fifty c.c. of normal human serum were injected subcutaneously during the first two days but as the hematomata were increasing in size and as the general condition of the child was worse seventy-five c.c. of blood were injected into the arm vein. Following the transfusion the hematomata gradually became smaller, the general condition improved, nursing was reestablished and no more subcutaneous hemorrhages were noticed. Its weight at birth was 4,170 grams, when transfused it was 3,820 grams and on the eleventh day it was 4,005 grams. The child was discharged in good condition on the twenty-first day. The physician reported twelve months later that the baby had been well since leaving the hospital and that it weighs twenty-two pounds.

Baby G. Was circumsized on the ninth day by a rabbi. It was admitted to the hospital bleeding from operative wound and all local attempts to control the hemorrhage were unsuccessful. At two A M. the following morning the child was pale, the general condition was poor, and transfusion was performed. One hundred and twenty c.c. of citrated blood was injected and the bleeding stopped at once. The patient was discharged four days after transfusion. The mother

reported to the hospital with the baby fifteen months later and said that the baby was well and that there had been no recurrence of the hemorrhage.

Baby B. Was delivered May 26 after a long labor by a medium forceps operation. On the second day it began to show symptoms of cerebral irritation. On the third day there was some hemorrhage observed beneath the scalp which extended downwards into the neck, at which time the temperature was 99.8° and the general condition was bad. Transfusion was done on the third day and sixty-five c.c. of citrated blood was injected. The following day the condition improved and the baby was discharged two weeks after delivery weighing 3,440 grams. It weighed 3,100 grams at birth. The physician reported eleven months later that the infant had been well since leaving the hospital.

Baby D. Was a difficult forceps delivery and definite symptoms of cerebral hemorrhage manifested by tense fontanelles, muscle spasm and convulsions developed during the first twenty-four hours. For the following thirty-six hours it was treated with normal human serum, at the end of which time it bled from the mouth, stomach and rectum. General condition became worse, transfusion was performed on the fourth day and eighty c.c. of citrated blood was injected. The coagulation time was twenty-five minutes before transfusion and four minutes following the transfusion. The baby was discharged well on the twelfth day.

Baby G. Was delivered March 1 by forceps. Extensive subcutaneous hemorrhages were observed in the back and neck on the third day. Serum was immediately administered early in the morning but the general condition of the infant grew rapidly worse. It was transfused with sixty c.c. of unmodified blood. The temperature on the morning of the transfusion was 101° and after transfusion it was normal. Sixty c.c. of serum was given in two doses on two successive days following transfusion. Its weight at birth was 3,150 grams and it was discharged on March 20 in good condition with its birth weight. The mother reported fourteen months later that the baby had been well since leaving the hospital.

Baby M. was a normal delivery. Hemorrhage began in the first twenty-four hours and it was very extensive from the mouth and rectum. Three hours from the time the first bleeding was observed transfusion was performed and one hundred c.c. of citrated blood was given. The following day twenty-five c.c. of serum was given subcutaneously. The baby lost little weight and was discharged on the tenth day in good condition. It was seen fifteen months later and the mother reports that it has been well since leaving the hospital.

Baby A. Was admitted to the hospital four days post partum with extensive hemorrhage from the umbilicus and marked anæmia secondary to this hemorrhage. It was at once transfused with one hundred c.c. of citrated blood and the hemorrhage from the cord ceased as soon as transfusion was completed. The cord came off without any further hemorrhage on the eighth day. The baby was discharged on the tenth day weighing 3,500 grams which weight it had when admitted. The infant also showed some jaundice on admission but this had almost completely disappeared when discharged.

Baby A. Was delivered by low forceps February 29. There was a small forceps abrasion on the forehead. The infant bled slowly from this abrasion and on the first and second days numerous increasing subcutaneous hemorrhages were observed in the neck, back, and face. The baby was transfused on the afternoon of the second day with sixty c.c. of citrated blood. Bleeding ceased while transfusion was going on. Twenty-five c.c. of normal human serum was injected on each of the following days for two doses. The baby continued to do well and was discharged from the hospital seventeen days after birth in good condition. A report twelve months later from the mother showed that the baby was well and had had no recurrence of its condition.

Baby K. Was a normal delivery on March 2. On March 3 it vomited considerable fresh blood. Two hundred c.c. of human serum was given on the third and fourth day but the hemorrhage continued from the stomach. On the fifth day seventy-five c.c. of citrated blood was given intravenously. It ceased bleeding, continued to nurse, and was discharged sixteen days postpartum in good condition.

Baby H. Male, colored, presented a cephalohematoma and multiple subcutaneous hemorrhages on the second day following a normal delivery. The general condition of the infant was poor and it was transfused at once with one hundred and fifteen c.c. of citrated blood. Twenty c.c. of human serum was given on each of the following two days. The infant weighed 3,780 grams at birth and was discharged on the fourteenth day weighing 3,910 grams. The mother one year later states that the baby died when seven months old from bronchopneumonia and up to that time there had been no recurrence of the hemorrhage.

Baby F. Was a normal delivery, showed numerous subcutaneous hemorrhages on the sixth day which continued to increase in spite of treatment with human serum. It was transfused with eighty c.c. of blood by the citrate method on the eighth day and it was discharged on the twelfth day in good condition.

Baby R. Was a normal delivery and six days later it began to bleed from the umbilicus. Forty-eight hours afterwards it showed marked anemia, some jaundice and the general condition was bad. It was transfused at this time with 100 c.c. of citrated blood. The baby did very well on the following day but on the second day it began to develop symptoms of cerebral hemorrhage. Subcutaneous injections of whole blood were administered at that time and were repeated, but in spite of this treatment the child died four days after transfusion from cerebral hemorrhage and anemia.

Baby W. Was a normal delivery and developed a large cephalohematoma which increased in size regardless of treatment by normal human serum for six days. The general condition of the baby grew worse and it was transfused with eighty c.c. of citrated blood. Normal human serum was injected subcutaneously after transfusion. It was discharged on the tenth day. Five months later the baby was in good condition and gave no history of a recurrence.

Baby K. Began to bleed ten days postpartum from the umbilical stump. It was treated with normal human serum for twelve hours but the general condition grew worse and it was transfused at once with eighty c.c. of unmodified blood. The bleeding stopped and the infant was discharged in three days. The baby returned two months later in good condition.

Baby D. Was a colored male infant and showed an extensive subcutaneous hemorrhage in the back on the second day. It was very anemic and sixty c.c. of citrated blood was given on the third day by transfusion. There was some febrile reaction two hours after transfusion. Baby was discharged eleven days postpartum.

Baby S. Presented a large cephalohematoma which gradually increased in size until the ninth day. There were also some small subcutaneouss hemorrhages. It was markedly anemic and the general condition was poor. It was transfused with one hundred c.c. of citrated blood after it had been treated with human serum for two days. The hematoma became smaller and the patient was discharged eighteen days postpartum.

Conclusions.—1. There is no definite etiology for the spontaneous hemorrhages of the new born, but both in this type and in the traumatic type bleeding persists because the blood system is not complete at birth. The addition of normal adult blood is rational therapeutics because it supplies the substances that are necessary to promote clotting.

2. The blood of both the infant and the donor must be examined for isoagglutinin before transfusion, with the same precision that is customary in transfusing an adult.

3. Sixteen cases of serious hemorrhage in the newborn have been reported with one death, and whereas in a large series of cases there would still be a definite mortality, the former percentage

has been greatly reduced by the intravenous administration of whole blood.

POST-PARTUM HEMORRHAGE (CERVICAL).*

By H. D. Fair, M.D.,

Muncie, Ind.

I do not intend to cast reflections upon the intelligence of this audience by quoting paragraphs from the various authors with which you are as familiar as I, neither will I copy from the pages of textbooks to be found upon your shelves, for you have access to these, and can consult them whenever you wish to do so, and should not be compelled, out of courtesy to the essayist or the occasion itself, to listen to quotations when you may not feel so inclined.

I do not know whether my early impressions received from instructors differed materially from yours or not. I see no good reason why they should, but for years the picture thrown on my mental screen by the suggestion "post-partum hemorrhage" was that of blood oozing or gushing, as the case might be, from the interior of the uterus, necessarily the placental site. As I recall the literature coming to my table fifteen to twenty years ago I remember that I was further impressed that the large number of case reports dealing with post-partum hemorrhage handled it as a uterine flux and nothing else. Of course some of those patients died and some are still dying, even though the uterine contractions would seem capable of closing any open uterine sinuses, yet we are led to infer that in some way or another the uterus was at fault.

At this time I want to call your attention to a type of post-partum hemorrhage in which the placental site plays no part; a serious type of hemorrhage made doubly so because its source was in times past and is occasionally today allowed to pass unrecognized and, as a consequence, untreated. I refer to damage done to the cervix, lower uterine segment, or some portion of the uterine canal known as the "soft parts."

I wish here to repeat an assertion made before this society in connection with one of my other papers, namely, the gods must have been particularly good to me, for during the first ten years of my practice I never took a stitch in a torn cervix and never lost a woman because of post-partum hemorrhage. Now take this record into consideration with the fact that during the past year I have seen five cases where prompt repair of the cervix was necessary, in fact the only thing that could save the woman's life, and furthermore the available time for effective action was limited to five or less minutes.

It now looks as if the gods had withdrawn their protection and are expecting me to recognize my responsibilities and make good without any providential help. If it is expected of me, why not of each of you who are doing obstetrics? Thus warned, we should go prepared to meet and care for any emergency. Some of us may argue and inquire, "What is the use of burdening ourselves with equipment and costly supplies which we may seldom need when we have capable surgeons within thirty minutes' distance?" It is true we may carry an instrument with us day after day for years and never have occasion to use it, yet the next trip it may become a life-saving implement. We may also go forth confident in the willingness of our able colleagues to come to our assistance at any time, yet the occasion may arrive when the necessary thirty minutes is a span that will be bridged by the death of our patient. In order to get this matter before you in a cogent manner I will take the liberty of reporting a recent experience.

This girl was a little past 17. She had reached full term for the third time; her first baby (now living) having been born a few days before she was 14. I had never seen her before the hour of her confinement on this date. When my assistant and I arrived the first stage was completed and the head was at the perineum. We worked rapidly but did not have time to make our usual preparations. The room was scantily furnished and the patient was on a low bed with sagging springs. A neighboring woman who had been present an hour or more kept insisting that the patient "bear down" although I instructed her not to do so. Following the expulsion of the fetus, which occurred about ten minutes after we reached the house, the hemorrhage was profuse so I hurried the third stage by the employment of Credé's maneuver, but the hemorrhage continued in spite of good contractions. Blood was spurting through the vulva in a jet. I put my fingers into the vagina and found a deep tear in the cervix; put my whole hand in and followed the rent up through the internal os into the lower uterine segment, where a branch of the uterine artery had been severed. I pinched the edges into as nearly an approximation as possible, and the hemorrhage lessened somewhat but whenever I released my grip the stream of blood shot out past my wrist, so I held fast while my assistant prepared suture, retractor, tenaculum, and Mayo clamps. With my hand still in position I reached in with a tenaculum directed by the other hand and grasped the torn edges, best I could, exposed the cervix all it would safely stand, then withdrew my hand. I inferred by this time that my patient was pulseless, for she had passed the point of resistance although I had not given either opiates or anesthesia, but I did not have time to verify my suspician for the hemorrhage still continued. By touch rather than by sight, for the vagina was full of blood, I placed a deep suture far up as possible in the apex of the wound, drew the knot tightly and had the satisfaction of seeing the hemorrhage practically cease. Now I felt that I could take a few seconds to estimate the condition of my patient who was apparently lifeless. The pulse was not perceptible at the wrist and the facial aspect was ghastly. I applied my ear to the chest and could hear but one heart sound and that faintly. I instructed my assistant to administer 15 minims of adrenalin solution while I finished the repair which required seven stitches. We then put the woman back in bed, elevated its foot, applied warmth, and began pouring hot milk betwen the patient's lips with a spoon. We kept this and other procedures up till there was a wrist pulse, but when we left the house we realized that we had a badly shocked patient. To shorten what might be made a long story I will simply say that this woman made a good recovery; but we all know she would have succumbed if I had not been prepared to meet the emergency promptly. There was no time to send for help. There was not one minute to spare.

Now to the point—what happened to me may

*Read before the Muncie (Ind.) Academy of Medicine.

happen to you. Every labor causes some damage to the cervix. Fortunately for our patients the tendency in small tears is toward spontaneous repair, although there always follows a material change in the shape of the external os. We all know that nature fails many times, and that our patients would be in much better position had we taken a few stitches, even though the damage was not extensive enough to result in hemorrhage.

The conditions favoring extensive laceration of the cervix may be grouped under five heads, the first ranking above all others in frequency and importance: (1) Rapid manual or mechanical dilatation; or forcible delivery before dilatation is complete. (2) Precipitate labor (involving the principles mentioned in 1). (3) Elderly primiparity. (4) Diseases of the cervix. (5) Disproportion between the passage and the passenger. The anterior lip may be caught between the fetal head and the pubis and be sheared off. Sometimes a portion of the cervix is dragged off the uterine body at the vaginal junction, and rarely the whole cervix may be amputated in the form of a ring.

The blood supply of the uterus, as you well know, is generous, the uterine artery itself crossing in front of the uterus less than one-half inch from the cervix. The cervical branch springs from the main branch as it crosses the ureter, passing directly inward and dividing into four or five branches, one of which anastomoses with its fellow of the opposite side, forming the circular artery of the cervix. Other branches unite with the arteries of the vagina which run along the median line of the vaginal wall, one anterior and one posterior. Why is it not good practice to ligate an exposed artery in this region when our surgeons are so careful to notice every little bleeder when doing any other operation? Good work on the cervix and vaginal vault requires skill and should be done by an operator who is careful of his technique; but in the event a laceration of serious degree occurs when the general practitioner who happens to be the accoucheur does not have time to get help, how is he to deal with the situation? He certainly does not wish to lose his patient.

The first essentials, of course, are the instruments necessary to meet the needs, such as a retractor of some sort, a vulsellum, clamps that will hold without severely bruising the tissues, needles, holder, suture material, scissors, and plenty of gauze sponges. If you do not have sterile towels, those freshly ironed may be substituted.

Many other things may be added to this list increasing the ease and efficiency of the operation, but in an emergency an operator might get along with a needle, linen thread, and pocket knife. I certainly would make the attempt before I would allow a woman's life blood to ebb away.

If possible have everything in readiness and your needle threaded before beginning the operation, for if you do not there is sure to be confusion, and the field of operation will stand a good chance to be contaminated. If short of assistance a sling can be easily made from a bed sheet that will hold the patient steadily in the lithotomy position. Every physician should know how to make this sling quickly. One of the important considerations is the placing of the patient. For any obstetric operation she should be placed on a table, or high reinforced bed, where a good light plays on the field of operation. It is presupposed that the patient has received the cleansing and preparation good obstetrics requires *before such an accident occurs*. The technique is simple but important. With the retractor expose the cervix if possible, then seize the presenting lip with the vulsellum and bring the injured surfaces into view, placing one pair of clamps on each torn edge in a way most likely to serve the purpose later on. If a bleeder comes into view, which is possible but not likely, it should be picked up and tied before the suturing proper is begun. The catgut should be a No. 2 chromic and the needle a short curved one, rather heavy and with a cutting edge or trochar point. The first stitch is by far the most important and should close the apex of the wound without leaving any dead space. The remainder of the operation is easy, but it may be later advisable to remove this first stitch and take another before satisfactory results are obtained.

The after care is simple. If it is a clean job the less subsequent attention the better the chances for a good recovery. If unfortunately the patient be infected she should be kept clean and as free from odor as consistent.

Once in a while some practitioner recommends packing the vagina as a treatment for hemorrhage due to laceration of the cervix. I consider this only a makeshift, for the lesion still exists and as long as it does exist is a menace, and a menace should not be tolerated.

Western Reserve Life Building

ORAL FOCI-PHOBIA.

By JOHN J. A. O'REILLY, M.D.,

Brooklyn, N. Y.

"INCREASE in function predisposes to disease" and decrease in function must tend to degeneration. It is true that babies are born toothless but if there be not some arrest to the tendency to rip out perfectly good teeth on the theory that they are foci of infection, "which send the pus all through the system" as Sairey Gamp tells us, I fear that coming generations will have to dispense with strong meat as we tailless ones have dispensed with limbs of trees as resting places, according to the Darwinists; therefore I wish to suggest some special team-work between the doctor and the dentist as a means of preserving and conserving teeth for toothsome tidbits.

The lower animals have no Riggs' disease—Why? Because Nature provides a way for maintaining the integrity of their body-chemistry and insures efficient economy of food-intake as to quantity and quality, provides for a high percentage of nourishment and a low percentage of waste and the prompt assimilation of nutriment and disposal of waste; with the lower animals vomiting is the corollary of over-eating, and abstinence the complement of satiety; they eat to live, while we live to eat or eat from habit. To be sure the lower animals are without mental anxiety concerning the butcher, the baker and the candlestick maker and rent-day means nothing in their young lives; but, with all the cares which civilized human existence

imposes upon us, we can still attain a measure of perfection in body-chemistry which will make for general health and oral cleanliness if we apply to the factory called the body a modicum of the attention which a corporation gives to the minimizing of waste and increase in output of a purely commercial institution.

The red cells of the blood have a dual function,—to bring oxygen, etc., to the tissues for their constructive chemistry and to utilize some of that oxygen for the destructive chemistry or dry-cleaning process which converts the dead meat of the tissues into an ultimate urea for elimination by way of the kidneys. But a red cell cannot be in two places at one time, "barrin' it is twins," and doubling its work halves its efficiency, so that imperfect end-product manufacture means greater by-product accumulation.

The small intestine may be compared to a freight railroad with a station for every letter of the alphabet; imagine a train, laden with food stuffs, served at Station A by two careless freight handlers, Bile and Pancreatin, so that a box of choice melons, for instance, is not digested off at Station A; apart from the malnutrition of the business of the consignee at Station A, that box of melons embarrasses the freight agents along the line and, getting in their way, impairs efficiency. When that train passes beyond Station Z and rolls into the terminal freight yards (colon) it should contain only legitimate waste,—empty barrels, boxes, broken crates, excelsior, paper, and twine; the neglected box of melons is extravagant and will be demoralizing because the 'cleaners-up' in that terminus (colon bacilli) are only human and will neglect the duty of moving the legitimate waste and indulge in the pleasure of a banquet upon the illegitimate waste (undigested and partly digested foods): This feasting results in the release of food gases which by expansion impair heart and lung action, and the development of toxins which threaten life and require blood-activity and oxidation to render them inert. You cannot have a battle of the Marne, and win it, without losing some soldiers, and you cannot have the battle of the colon, and win it, without losing some red cells; this means actual reduction in the quantity-oxidizing-power of the body and, by reason of overwork, a reduction in the quality-oxidizing-power which makes it necessary for the red cells to apostrophize the tissue cells, dying in the performance of their functions, thus:

"I am sorry, I would like to do my full duty by you and oxidize you to an ultimate urea but a riot threatens in the colon; I will digest you to a salt and stick you away in the interstices of passive white fibrous tissue; in sheaths of muscles, tendons, nerves, and blood vessels; in the sarcolemma of voluntary and involuntary muscles; in the capsules of joints; in the scalp; in the tonsils; in the gums and linings of alveolar cavities, and I will come back tomorrow and complete my work of oxidizing you to an ultimate gas-urea."

But to-morrow's story is the same as to-day's and instead of redeeming these promissory notes, more and more are issued with a resulting rheumatism or acidosis (call it what you will—the pain is the same to the sufferer), or a maddening scalp headache, a tonsillitis, or a Riggs' disease: It is not difficult to understand that the presence of this foreign material in the oral tissues not only impairs the chemistry of the saliva and reduces its germicidal power, but it supplies the physical irritation with its resulting insidious inflammation and contraction which accounts for the retraction of the gums at the base of the teeth (and the loss of the cosmetic festoon of gum and its practical 'hug') with a consequent exposure of a greater area of tooth surface and the boring of germ-life into the alveolar cavity where the microorganisms thrive prodigiously and well up their pus-products for absorption by the blood, for the lessened alkalinity of the mouth juices, with its attendant impairment of beginning starch digestion and its subsequent inhibition of the gastric fluids, thus sending food material into the small intestine imperfectly prepared for digestion by the already inefficient freight-handlers, Bile and Pancreatin, and the vicious cycle is complete.

Obviously, treatment limited to the mouth is treatment of a symptom, not a cause. Here, it would seem, that the blend of medical and dental citizenship might properly be expanded to embrace a blend of medical and dental scientific cooperation, and wherever a dentist is called upon to treat such a mouth condition or a doctor to treat such a constitutional condition of bad body-chemistry, each, in justice to the patient and to himself, should recommend a blend of medical and dental care, precisely as we would wish a mechanic, grinding the valves of our auto, to direct our attention to some ignition defect which might be remedied by one who knows, to the greater efficiency of the machine as a whole.

Obviously, too, the routine use of cathartics by a patient merely empties the colon but makes no appreciable impression upon the existing defect in the organ "higher up."

It would seem that the systematic exhibition of cholagogues plus diminishing cathartics with suitable tonic treatment and recommendations with regard to the quantity, quality, and regularity of food, work, recreation, and rest, in so far as practicable and reasonable, with the urgent recommendation that the local condition in the mouth receive the attention of the family dentist is the doctor's duty and the patient's right; then it becomes the patient's duty to do his part in preventive medicine and, seeking out his dentist transfer to him the duty of improving the mouth condition. In like manner where the initial observation is with the dentist he should warn his patient of the constitutional element. Because of the element of personal interest which endears the family doctor and dentist to the people and forms the basis of their non-partisan endorsement of our Campaign of Education, it is not difficult to imagine a phone conversation between them with the patient as the subject which in a few moments sets the stage for true cooperationism and real Preventive Medicine.

This is just one facet of the solution of the sickness problem which in all humility I offer you.

Digestive Ferments in Ozena.—Pepsin and trypsin have been used to dissolve the crusts of ozena, the former in combination with boric acid and the latter with sodium bicarbonate and lactose. Pepsin is said to give the better results.—*La Riforma Medica.*

TONSIL HEMORRHAGE:

WITH A NEW PROCEDURE FOR THE CONTROL THEREOF

By ALFRED KAHN, M.D.,

NEW YORK.

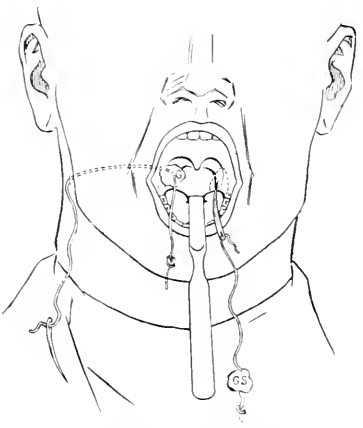
THE human mind is possibly the most changeable thing in the world. The mind of the individual is contradicting itself every second. The fundamental laws of to-day are the errors of to-morrow. Opinions vibrate from one extreme to another. In short, right is wrong and wrong is right.

Ten years ago tonsil removal was easy. It was the easiest operation in the category of surgery. Anyone not able to do a tonsil operation with his eyes closed was not considered deft, but was considered below par. He was a surgeon of the eighth degree of inefficiency.

To-day the pendulum has swung the other way and the tonsil operation is considered serious—to be done with the greatest of caution, under the most favorable surroundings, by the most skilful of specialists. The tonsil is not to be trifled with. It can almost be said that every case offers a different angle. Or rather, the exceptions to the rule make careful observation and keen judgment an absolute necessity to a successful ending. The average operation, the average tonsil removal, is easy, and nine cases in ten will not cause any trouble. But occasionally the exceptional case comes to hand, and this is the case that tries the soul of the surgeon. The complications are innumerable, and often they may come so fast and unexpectedly that the surgeon is almost thrown into a state of shock. Perhaps the most serious complication is severe hemorrhage, and it is of this complication I desire to speak a few firm words, which I think will be of value to others doing this class of work.

Argument to the contrary notwithstanding, removal of tonsils under local anesthesia is more dangerous ten to one than under general anesthesia. On this point I have completely reversed my former opinion. In the past I was an advocate of removal under local anesthesia. If adrenalin is used in the local injection, the danger from secondary hemorrhage is increased perhaps another 10 per cent. Removal of tonsils under local anesthesia in the presence of an infection increases the liability of secondary hemorrhage. It may happen in the presence of long standing infection in the region of the tonsil that the surgeon cannot estimate how deep or widespread the infection is. This class of infection (although very rare) often burrows deeply and now and then, once in a number of cases, necroses the large vessels in the neighborhood. These rare cases are extremely dangerous. The patients suffer from a chronic toxemia and are often quite anemic. They often show glandular involvement and they may die before they come into the hands of the surgeon. When they reach the surgeon, the usual inflammatory signs are wanting. In fact, the surface markings in the throat are almost nil. The tonsil may be pushed forward as in a peritonsillar abscess, or there may be some edema in the tonsil region; but the actual red, heated appearance of an acute inflammation is not present. If the tonsil is removed a process of necrosis (of sloughing) will be found back of the tonsil. Very little or no pus may be found. The infecting germ is perhaps of the streptococcus class. In this type of case, hemorrhage is apt to occur primarily at the time of the operation, if done under a general anesthetic; or if done under a local anesthetic, it may occur secondarily during the process of reorganization. If the hemorrhage is of an oozing character, it can be controlled by fastening a gauze sponge in the cavity, after the tonsil is removed, by the following original method.*

A gauze sponge is attached to one end of a strong piece of silk or kangaroo tendon. At the other end of the silk or tendon is a needle as per illustration. The needle is passed through the mouth to the tonsil wound, through the tonsil cavity, through muscle and skin to the outside. The gauze sponge is pulled into the tonsil cavity, until it fits it snugly and firmly. The string is fastened on the outside of the neck over a button or gauze pledget, or it may be carried around the back of the neck, where it meets a similar string passing from the opposite tonsil; and they are both attached together at the back of the neck. The gauze sponges in the tonsillar cavities give the larger vessels support (acting as a splint),



at the same time presenting a meshed supporting surface to aid the process of coagulation. When the patient swallows, the coagulum is not each time swallowed, but sufficient coagulative blood is held in the sponge to stop the bleeding. Of course, if there are any large individual vessels spurting, they should be tied. This method is recommended only in cases of oozing over a large surface, and to support the reorganizing tissues until all danger is passed.

Again the rare case. Recently several cases of cavernous sinus thrombosis have been reported following tonsil enucleation. Recently cases have been reported of disease involving the large venous channels of the neck following enucleation. Meningitis has been reported, metastases in distant portions of the body have been reported, following tonsil enucleation. A remark in this regard. Do not manipulate roughly, or to any extent, in a tonsil cavity after the tonsil is removed. Remember that a squeezed tonsil before its removal is still attached

*This method was described at a meeting of the New York Physicians' Association, April 28, 1921.

to its blood supply. Remember that nearly all tonsils are a focus of infectious organisms and that they can be squeezed into the blood stream. Especially bear in mind in the presence of infection, not to manipulate the tonsil any more than necessary, nor the wound after the tonsil is removed. When a bad hemorrhage occurs, especially in the presence of an infection, do not manipulate the wound at all. If the bleeding vessel or vessels are deep in, high up, where they cannot be tied off, or where if they can be tied off only by a great deal of manipulation, and where there is a possible chance of the ligature slipping away and allowing the hemorrhage to occur again, the surgeon should make up his mind quickly, decidedly, and firmly, he should immediately tie off the carotid.

This last statement will make my surgical friends shudder. But I am firmly convinced a scar on the neck is better than a dead patient; I am firmly convinced and I say it unhesitatingly, that ligating of the carotid is one of our best instruments of attack in this type of case. The throat surgeon should be able to do a carotid ligation as readily as a tonsil enucleation. No man likes to incise the neck of a patient on whom he has performed a tonsil operation. The public should be taught that tonsil enucleation is an operation of the first degree, and that complications occasionally arise. It is well to teach them this early. They can then sensibly cooperate with the surgeon. They would then realize, with good judgment, that the surgeon occasionally finds it necessary to do unexpected things, which he could not foresee at the time of the original operation. The public will eventually learn for themselves, and they are beginning to learn more and more each day, that accidents do happen, and it is far better for them to learn the subject in a clean, manly way from the surgeon than in a vulgar, critical light.

Finally, as a last parting word, in the face of the hemorrhage, in line with the conditions and surroundings mentioned, I want to emphasize that most effective procedure, easily done—the tying of the carotid.

THE THERAPEUTIC APPLICATION OF GALVANO- AND FARADOPALPATION.

By MAX KAHANE, M.D.

VIENNA.

The want of definite rules in the practice of electrotherapy is due to the fact that no given principle as to the application of the electric current has found general acceptance; and consequently there has been the widest difference of opinion as to the intensity of current to be employed and as to the duration of the applications; extreme differences, also, as to the technique have led to the opinion that electrotherapy lacks real efficiency and that any curative effects that may be obtained are due solely to suggestion. And recently even the differences in the effects of the anode and the cathode, on which the indications for galvanotherapy are based, have been called in question; so that now uncertainty invests something as to which there has heretofore been a certain amount of agreement.

A favorable development of electrotherapy can be attained only on the assumption of certain fundamentals. Personal experience extending over thirty years has convinced me that the attainment of cures is essentially dependent on current density and that current intensity (strength) is of little significance. Maximum current density is obtained by a minimum of electrode surface. It is therefore necessary to employ an extremely sharp-pointed electrode, either in the shape of needles or very sharp-pointed button electrodes. An ordinary sewing needle mounted in the needle holders employed in electrolysis will answer the purpose admirably. One who has seen the powerful effect produced by a needle electrode even with the application of such a weak current as 1 milliampère becomes convinced that maximum current density corresponds to the requirement of maximum energy of effect. All that can be accomplished with large electrodes, strong currents and long applications, can be attained by the use of the principle of maximum current density, weak currents and short periods of application; the principle is therefore economical as to time as well as to energy.

The intensity of the effect achieved by this principle of maximum current density may be augmented by a second principle: palpatory application. Palpatory application consists essentially in applying the current by a frequently interrupted tapping motion at the site of the application. It is essential to this method of treatment that the current be applied suddenly; contrary to the ordinary procedure, the current is not made and broken; the desired current is obtained by first applying the treatment electrode to an indifferent area, turning on the current, and then applying this electrode to the desired area (*i.e.* the area to be treated) after the desired current intensity has been obtained. Maximum current density, palpatory application and suddenness in the application of the current increase to the maximum the intensity of the effect produced by the current, this being due to the fact that currents of 4 or 5 milliampères evoke very intense reactions. The principle applies to the galvanic current as to the faradic current—to galvanopalpation as to faradopalpation.

The application of galvanopalpation for diagnostic purposes was described by me in the Medical Record, Dec. 18, 1920. Faradopalpation has only therapeutic interest.

Galvano- and faradopalpation are therapeutically indicated in those conditions in which a powerful stimulation by electricity has proved of service above all in paralyses and neuralgias, *i.e.* in the two most important electrotherapeutic domains. As regards rapidity and intensity of effects the best results in these maladies are obtained if both galvano- and faradopalpation are applied at the same session. This method is of value even in those cases in which the usual methods of treatment have failed, *e.g.* paralysis with reactions of degeneration, inveterate neuralgias (trigeminal neuralgia, neuralgia after herpes zoster), etc. By long continued galvano- and faradopalpation it is possible to cure cases of even well advanced muscular atrophies. In cases of pruritus vulvæ and pruritus ani the application of faradopalpation (spark discharges from a needle electrode) has a curative effect which may be designated as specific.

One of the most important features of this principle of treatment by maximum current density is the fact that any desired spot can be treated with full energy. This is of special value in the treatment of facial paralysis, inasmuch as each single muscle bundle can be made to contract separately. In the treatment of neuralgias it is essential first to determine the locus effectus by a galvanopalpatory exploration and to apply the therapeutically effective current in the right situation and under the guidance of the vascular reaction. This applies especially to the peripheral neuralgias where galvanopalpation enables us to determine with certainty whether an existent neuralgia is located in the spinal roots, in the plexus or in the peripheral nerves. One who treats a neuralgia without having first investigated it by galvanopalpation is substituting pure accident for success-ensuring scientific technique. We have already mentioned it that even the most difficult neuralgias, trigeminal neuralgia and neuralgia following herpeszoster, such quick and satisfactory results can be obtained from combined galvano- and faradopalpation as can be obtained from no other method of treatment. It is especially noteworthy that in these neuralgias the patients are relieved at once by the treatment, are freed from pain for several hours and are able to eat and sleep. As the treatment is continued the attacks of pain come less and less frequently, get milder and milder in intensity, and essential improvement is obtained even in cases in which, owing to the nature of the malady, a complete cure is unattainable.

In the treatment of neuralgias and paralyses applications of a few minutes' duration suffice; two to three minutes at first, and five to six minutes later on. An average current intensity of one to two milliampères is all that is required; in very severe neuralgias three to four milliampères may be employed. Particularly strong effects are produced by the sparks discharged from the needle electrode in faradopalpation; as to this the distance between the coils is to be such that the patient may be able to endure the sparks. The use of a needle for faradopalpation is indicated in neuralgias especially; in the treatment of paralyses it is best to employ a very sharp pointed button electrode covered with canvas or leather—an electrode which also works energetically and is better borne than the needle electrode.

In my opinion the superior therapeutic efficacy of palpatory electrotherapy is chiefly due to the strong cutaneous reaction which manifests itself in the form of an intense and long lasting active hyperemia. By galvano- and faradopalpation degrees of hyperemia may be obtained which can otherwise be obtained with the same rapidity only by strong mechanical, thermic or chemical stimulation. The assumption is probably justified that electropalpation is indicated everywhere where a local active hyperemia is desirable, so that the sphere of its usefulness ought to be considerably enlarged. In addition to the hyperemia the immediate strong stimulation of the cutaneous nerve endings is probably also of significance. Experienced observers are of the opinion that the electrochemical effect of the galvanic current is an important factor in the curative effects it accomplishes.

Medicolegal Notes.

Food and Drugs Act—Inducement to Violate by Government Agent.—The Federal district court for the District of Colorado holds that a manufacturer of a medicinal preparation was not chargeable with violation of section 8 of the Federal Food and Drugs Act, as amended, by the shipment of a misbranded article in interstate commerce, where the only shipment of this character shown was on an order sent from another State for the purpose of entrapment by a Government agent, who had no reason to suppose that the defendant had ever previously made such a shipment.—United States v. Eman Mfg. Co., 271 Fed. 353.

Consideration for Check for Hospital Expenses Paid in Advance.—Where a husband, at the solicitation of his wife, executes a bank check, payable to "Cash," and delivers it to her, for the express purpose of paying in advance a week's expenses of her father at a hospital where the father is then lying critically ill, the rules of the hospital requiring such payment to be made in advance, and she delivers it to the owner of the hospital for the purpose stated, and the father is cared for in the institution until his death, which occurs after her delivery of the check, but upon the same day, the Georgia Court of Appeals holds that the check is not without a valid consideration. And where the owner of the hospital presents the check to the drawee for payment, and payment is refused because of an order of the husband to stop payment, the owner of the hospital is entitled to recover from the husband the face value of the check. The court considered the check was based on at least two valid considerations: (1) The agreement to keep the defendant's father-in-law in the hospital for another week, and (2) the benefit flowing to the defendant from the granting of his wife's request to pay her father's hospital expenses for another week.—Lingo v. White (Ga.), 106 S. E. 312.

Minnesota Statute Regulating Dispensation of Habit-Forming Drugs Held Not to Conflict with Harrison Act.—The Supreme Court of the United States holds that a State, in the exercise of its police power, has authority to regulate the administration, sale, prescription and use of dangerous and habit-forming drugs in the interest of public health and welfare. Section 2 of the Minnesota statute of 1915, c. 260 (sections 8965-2), prohibiting a physician from furnishing drugs to habitual users, though authorizing him to give prescriptions therefor in good faith, does not interfere with the enforcement of the Harrison Act, and there is no conflict between the enactments such as will prevent the State from enforcing its own law on the subject. The provisions regulating the sale, dispensation and disposition of the prohibited drugs are somewhat different in the two acts. The prohibitory measures of the Federal statute do not apply to the disposition and dispensation of drugs by physicians registered under the act in the regular course of professional practice provided records are kept for official inspection. Under the State law physicians can furnish only prescriptions to addicts, and may not dispense the drugs to such persons at pleasure from stocks of their own.—State of Minnesota v. Martinson, 41 Sup. Ct. 425.

Consideration for Subscription to Charitable Hospital.—In an action against a residuary legatee upon a subscription to a charitable hospital, the New Jersey Court of Errors and Appeals holds that, while such a subscription stands on the same footing as any ordinary contract in requiring a legal consideration and acceptance to support it, in this class of cases, the courts lean toward sustaining such contracts. And where, as in this case, the jury might have found that the subscriber to a charitable hospital stipulated as a condition of the promise to contribute to the building fund that her subscription was to be applied to the building of an operating room to be named by her, and that the hospital authorities were to obtain the waiver in her favor of a similar privilege held by another subscriber, there was evidence of a legal consideration, and it was error to nonsuit because no consideration appeared. Judgment for the defendant was therefore reversed.—New Jersey Orthopaedic Hospital and Dispensary v. Wright (N. J., 115 Atl. 144).

THE OYSTER.

MEDICAL zoology is one of the newer studies of the curriculum of the modern medical school, but thus far has been limited to medical entomology, with special reference to disease-bearing insects and to the larger parasites, chiefly worms, which cause disease. That in time this branch of medicine will be studied along the broadest of lines is apparent to any one who covers current medical literature. Here would most assuredly belong the part played by the domesticated animals in the causation of human disease, and one may think of the oyster as domesticated, and as an occasional cause of disease as well as an immune carrier. The *Journal de Médecine* de Bordeaux for May 25, 1921, xcii, 10, reproduces a lecture on the oyster by Dr. Llaguet in which the mollusk was considered from the biological, alimentary, medical, and economic angles. Of the two principal divisions of the oyster family, one known as the Portuguese or non-edible oyster need not be specially discussed. The belief that the latter had been made edible at times in the past by crossing with the edible oyster is no longer held. The oyster is an hermaphrodite but is not self-fecundating. The male principle dies first, leaving the mollusk female for the rest of its life; and crossing is indispensable for the conservation of the race. Each oyster may give birth to not less than a million embryos. These swim about until the shell appears and the age of the oyster may always be told accurately by the thickness of the latter, as well as by its length. Complete maturity is reached at ten years, but the duration of life may be from twenty to twenty-five years. If left to itself the oyster forms beds, and before 1850 all beds, at least in France, were natural. Artificial beds are intended of course to increase the supply for food purposes.

Of the numerous enemies of the oyster its cousin the Portuguese is one of the worst. It is far more fertile and noted for its voracity. Its extreme fertility is due to the fact that it breeds two or three times a year instead of once, like its edible cousin. The antagonism of the Portuguese oyster to the development of the edible oyster is due to the fact that it deprives the latter of some of its natural food and this is also true of the mussel and other shell-fish. Other mollusks like the starfish prey directly on the oyster, perforating the shells of the younger members, while the latter are also vulnerable to the attack of crabs. Certain flatfish make terrible havoc among oysters, destroying them by thousands in a single night. The mollusk is also subject to a number of diseases, being the object of attack by fungi and bacteria. Strange to state, however, these proper diseases of the oyster do not render it unfit for human consumption. The author states that he has eaten technically diseased oysters without experiencing the least inconvenience, and has fed them repeatedly to cats which also showed immunity. Yet the germ diseases are sufficient to have destroyed in certain years as high as 60 per cent. of the crop. Not all biologists, however, admit that a germ disease is involved in this mortality, and some have invoked meteorological conditions in explanation. High mortality has also been imputed to a recent tendency to spawn twice a year instead of once, which has always been the rule with the edible bivalve. Spawning thereby occurs in the late spring and early fall instead of in the summer, and this for one or another unexplained reason appears to be disastrous to the embryo.

Llaguet describes at length the artificial culture of the oyster, which must be passed over, coming to the problems of most interest to the medical man. The oyster does not appear in the market during the summer, not because it is inedible but because it is the reproductive season. It is true that they are less savory during the hot weather but that they can be eaten to any extent during this period with perfect impunity is well known to all authorities. At rare intervals and in response to special demands they have been eaten freely by the public during the hot months, as in 1900 when there was a World's Exposition at Paris.

The oyster is a stimulant to the stomach, a true stomachic, which can increase the flow of pepsin and HCl in those who are below par in this respect. It contains iodine, iron, phosphorus, and lecithin and the medical practitioners near the great oyster industry of Archachon prescribe them in habitual dyspepsia and tuberculosis. Oyster shell is also given in affections characterized by decalcification. The two great practical subjects in connection with oyster consumption are oyster poisoning and typhoid fever. In regard to the first named there is no doubt that decomposed oysters can give rise to a form of ptomaine poisoning. But fresh living oysters cannot possibly give rise to poisoning (except as they are carriers) and it is simple enough to determine their freshness and viability. Oyster typhoid is a well known fact and is combated either by flushing or irrigating the mollusks with disinfectants or by placing them in clean running water. The use of beds inaccessible to sewage is of course the ideal preventive, and in the great French industry at the Basin of Archachon the conditions are said to be ideal in this respect.

PATHOGENESIS AND SYMPTOMATOLOGY OF INTERLOBAR PURULENT PLEURISY IN CHILDREN.

PURULENT interlobar pleurisy may be a primary or secondary process. The pleura belongs to the system of serosæ and can react on its own account, hence primary pleurisy is more common, according to Dieulafoy, than the secondary. Netter, however, says that it is probable that pleurisy, idiopathic in appearance, is often preceded by an unrecognized pulmonary lesion, like apical or central pneumonia. Interlobar purulent pleurisy with Koch's bacillus is rare, although cases of pleurotuberculosis with a parietal onset in which the collection becomes encysted have been reported. The secondary forms follow pulmonary lesions or those in neighboring organs and general infections. Pneumonia is the commonest cause and the pleurisy will arise from direct extension of the infection or through the circulation. Bronchopneumonia is more prone to give rise to generalized pleurisy. Partial pleurisy may result from tuberculosis or pulmonary gangrene, although this is very rare. Lesions of the ribs, esophagus, tracheobronchial lymphnodes, and abdominal viscera have been incriminated and also certain general infections—typhoid fever, influenza, eruptive fevers, septicemia and pyemia; the bacteria of the primary process or an associated infection have been known to cause interlobar suppuration of the pleura, but the predominating fact is that whether primary or secondary, interlobar purulent pleurisy is usually pneumococcal. The pneumococcal collection becomes readily encysted because false membranes are deposited on the edges of the interlobar clefts, isolating them from the general pleural cavity, and thus a favorable nidus is created for the development of the pneumococcus. The cavity thus formed is usually single, but it may be irregular, formed by several pockets opening into one another, the amount of pus contained being often very considerable.

The symptomatology of interlobar pleurisy is rather varied; the process may remain latent and suddenly reveal itself by purulent expectoration. In other cases, after a pneumonia or other infectious process, the thoracic pain and bad general condition of the patient call the physician's attention to the lungs. Or the process may have a sudden onset. The patient, who was in good health, is seized with chills and a temperature around 103° F.; dyspnea and pain in the chest add to the symptoms of a general affection the characters of a pulmonary process; the cough is dry without expectoration. At the onset, when the collection is still small, the pulmonary phenomena present overshadow the lesion. Diminution of resonance, moist and sonorous rales, and a sibilant respiration indicate pulmonary congestion, and only a few friction sounds indicate the participation of the pleura. It is only after the collection has increased that the characteristic physical signs appear, but the classical signs of a fluid collection are not complete, because the fluid is separated from the stethoscope by a certain thickness of pulmonary parenchyma which weakens the sounds. Vesicular murmur is diminished and absolute respiratory silence may be met with. In cases of left sided interlobar pleurisy Traube's space remains sonorous. The collection which dips deeply down toward the mediastinum explains why, when on the left, the heart is pushed to the right as if the amount of fluid were considerable, whereas in children it rarely reaches 200 c.c. Dieulafoy thought that dyspnea was greater in this interlobar form than in ordinary pleurisy.

Hemoptysis may occur in interlobar pleurisy; the loss of blood may be severe or recur at more or less long intervals; it may precede or follow cavity formation, and in the latter case is due to an ulcerative process attacking the walls of the cavity. Purulent expectoration is the rule in interlobar collections, exceptional in ordinary pleurisy, and occurs two or more weeks after the onset of the disease. The fetid odor of the breath and sputum are the precursory signs indicating the formation of a pleuropulmonary sinus. After an abundant expectoration the ordinary stethoscopic signs of a cavity will be found, and Mery has pointed out that as the interlobar cavity fills a progressive decrease of the physical signs is noted, while the maximum of signs of a cavity, much more distinct than what might have been expected on account of sclerosis of the walls and pleura, indicates the emptying of the cavity. The rise of temperature, sweating, and chills become more marked as a cavity formation is nearing. Then after this has occurred all the symptoms progressively subside. The cavity is a reaction of the defense of the organism which brings about recovery, but if the cavity is not completely emptied the patient becomes infected and surgical interference may be indicated, the indications for operation being derived from the gravity of the patient's general condition.

HERNIAL APPENDICITIS.

ALTHOUGH the presence of a normal appendix in a hernial sac does not offer any pathognomonic sign, the same cannot be said when the organ is the seat of an inflammatory process. The patient will be suddenly seized with pain in the hernia which is increased by pressure. Some observers regard the character of this pain as having a considerable diagnostic value; it is not, as in ordinary strangulated hernia, even and without exacerbation, but on the contrary presents paroxysmal attacks superadded to the constant pain complained of, and this sign should invariably lead one to suspect hernial appendicitis. The pain is rarely localized and according to the site of the hernia, shoots in different directions. In umbilical hernial appendicitis there are diaphragmatic and intercostal neuralgic pains, lumbar and femoral pains as in inguinal and femoral hernia. There is also cutaneous hyperesthesia as in ordinary appendicitis. The size of the hernia increases and it becomes very hard to the feel;

there is also dullness on percussion. Bilious vomiting ensues, the pulse is rapid and the temperature oscillates between 101° and 103° Fahr. When nothing but the appendix is in the sac, no phenomena of general peritoneal reaction are observed, and this is a fact which it is important to bear in mind.

The appendicular process may subside, but should it progress serious complications arise in a few days. The skin becomes red, hot, edematous, offering the aspect of an abscess, and soon ulcerates, giving issue to pus and bits of sloughing appendix. The resulting stercoral fistula may persist or close spontaneously. There is yet another much more serious complication which will ensue if early operation is not resorted to. Given the symptoms, strangulation may be suspected and if taxis be attempted instead of operation a high grade peritonitis results. In the case of umbilical hernia a phlegmon may develop, followed or not by stercoral fistula. In femoral hernia with phlegmon, perforation of the femoral vessels has resulted followed by general infection.

When the sac contains the appendix with other portions of the intestine the local symptoms will be those of strangulated hernia, but the phenomena of peritonal reaction will be marked, manifested by vomiting, abdominal distention, and incomplete occlusion. When left alone, if adhesions have had time to develop at the neck of the sac, the process becomes walled off from the peritoneal cavity, so that an abscess develops in the sac, followed by stercoral fistula. When adhesions do not develop the septic products invade the peritoneal cavity, followed by general peritonitis and usually death. Strangulation of an appendix contained in a hernial sac is a rare event, but although denied by some, it does occur.

The lesions found are those met with in strangulated gut. In two cases recorded by Polloson a furrow was found in the appendix at the level of the ring while the organ was turgescent like a strangulated coil of intestine. The local and general signs of strangulation of an appendix in a hernial sac are those of ordinary hernial strangulation; but the abdominal phenomena are less marked; complete intestinal occlusion never ensues and vomiting never becomes fecaloid. The general symptoms vary in their appearance but are less pronounced than in intestinal strangulation, and in general, the aspect of the case seldom assumes the gravity of intestinal strangulation.

There is a peculiar form of strangulation of the appendix which should be mentioned, namely, retrograde strangulation, the pathology of which is far from clear. If the appendix, when once seated in a hernial sac, should fold upon itself, a loop will be formed which will be contained in the sac, while the proximal end and distal end of the appendix will remain in the inguinal or femoral canal. Should strangulation occur at the distal end it will be retrograde.

A New Calomel Treatment of Typhoid Fever.

A quarter century ago the treatment of typhoid fever by the calomel method of Woodbury was being freely discussed and applied, although with the death of its advocate it fell completely into oblivion. The theory upon which the drug was given was sound enough—the attempted sterilization of the intestine, and danger from hemorrhage, such as might conceivably follow the use of a purgative, was apparently not to be feared. The results were equivocal and unconvincing for the majority of those who tested the remedy. The technique for giving the drug was complicated and burdensome. In *Il Policlinico* for July 11, 1921, xxviii, 28, Galata, a physician in the Italian naval reserve, recapitulates his original experience with intramuscular injections of calomel in nine cases of typhoid during the year 1917, and adds considerable new material. His total now amounts to more than 300 cases, including those of several colleagues who tried out the method. The number analyzed is limited to 234 cases seen in thirteen hospitals with the very low mortality of four, or 1.7 per cent. Of the four fatal cases, bronchopneumonia was present in three. In addition to the preceding figures there were sixty-two cases treated at Trieste in which no mortality is mentioned, although it is apparent that in fourteen there was no marked response to the treatment. The author made his diagnosis in every case by seroreaction and hemoculture. He noted improvement after the second injection and a rapid and notable abbreviation of the usual course of the fever, so that defervescence followed the fourth and sometimes even the third injection. The drug was well borne with only a few cases of soreness of the gums and no other evidence of overaction. Intervals between injections were three or two days according to circumstances. The dose per injection was ten cgm. for adults in liquid vaseline, the calomel being associated with a like amount of equal parts of camphor and guaiacol.

Rhinopharyngitis in Kidney Disease

We do not recall that stress has ever been laid in native literature on this disease-association, for owing to the great frequency of postnasal catarrh in the United States it would hardly occur to any of us to associate it with particular types of constitutional disease unless there was some obvious reason for the coincidence. A recent article by Flurin, noted in *Le Progrès Médical* for July 2, 1921, xlix, 27, is devoted to the subject. He finds the association sufficiently common for diagnostic significance—that is, the presence of the nasopharyngeal lesions suggests to him that a renal lesion is also present. Necessarily this nasopharyngitis is of special types, associated with hypertension, chloruremia, or azotemia. It appears that pioneer rhinologists like Fauvel reported a reddened pharynx as highly suspicious, and they at once caused the urine to be examined in all such patients. One French specialist, Garet, made important contributions to the subject. This lesion has apparently no necessary connection with pharyngeal edema seen in anasarca with chlorine retention, in which condition edema of the glottis is a more

striking and serious symptom. However, Widal, a leading authority on chloruremia, mentions the existence of a rhinopharyngitis with hypersecretion as a forerunner of edema. It is believed that the extreme rhinorrhea sometimes seen at this period in compensatory, like other excretion in excess, for the inactivity of the kidneys. An analogous lesion is the so-called albuminuric bronchitis. In regard to a possible rationale for nasopharyngitis in Bright's disease, it has been attributed to the irritating action of eliminated chlorides on the mucosa. Finally in actual uremia the nasopharyngeal region is unnaturally dry and shiny with a sense of heat and burning.

Role of the Phlebotomus in Disease.

This insect, known to Anglo-Saxons as the sandfly, attained prominence at the outset of the influenza pandemic of 1918, which was supposed on its initial appearance in parts of Italy to be pappataci fever, a mild affection known to be due to the activities of the insect in question. In *La Presse Médicale* for July 13, 1921, xxix, 56, Joyeux, an authority on tropical disease, gives some space to the latter. There are at least thirty-two species and eight varieties known throughout the entire world. They sting during the summer months in temperate zones and in the tropics for a much longer period. Although in addition to man they sting other mammals, their predilection appears to be for the cold blooded animals and notably certain species of lizard. Like mosquitos they are nightfliers by preference. As breeding places they prefer old walls, especially when covered with vegetation. Despite the fact that the sandfly is frequently mentioned as a possible carrier of other diseases, thus far the only one for which it is known to be responsible is the three-day or pappataci fever. It does not carry malaria under any circumstances, and as for dengue, Joyeux states that he regards the latter malady as due to the activities of a *Stegomyia*—no other in fact than the one known to carry yellow fever, the *S. calopus*. In passing, the author quotes the recent theory that dengue is only an attenuated form of the more deadly malady. He also acquits the phlebotomus of transmitting forms of leishmaniasis and verruga peruana, as no direct evidence of such pathogenicity has ever been adduced.

News of the Week.

Smallpox Epidemic in Chili.—Santiago, Chili, is suffering from an epidemic of smallpox which is reported to be growing in intensity. The ratio of infection is about two to each 1000 inhabitants. The authorities are making strong efforts to prevent the spread of the disease by a campaign of vaccination.

A New Career for Medical Men.—A Royal Air Force Medical Service has been organized in Great Britain and general regulations governing it have been formulated. This opens up a career for medical men which should prove both attractive and interesting, and one which will provide much scope for research. The establishment consists partly of permanent and partly of short-service officers. Short-service officers who are approved for permanent commissions, but for whom there are no vacancies in the Royal Air Force Medical Service, may, under certain conditions, transfer to the Royal Army Medical Corps, counting the time served in the Royal Air Force Medical Service towards increments in pay and retired pay in the Royal Army Medical Corps. The rates of pay rise from 24s. a day on joining as flying officer to 60s. a day on promotion to group captain. The maximum retired pay for captains retiring at fifty-five is £900. For service in India the pay rises from 650 rupees per mensem as flying officer to 1950 as principal medical officer. Certain gratuities and the usual allowances granted to officers of other branches of the Royal Air Force are provided for.

Antiprohibition Vote in Quebec.—Ninety per cent. of those who voted in Quebec on September 13 favored the abolition of the Scott temperance act, which for the last three years has prevented the purchase of liquor without a doctor's certificate. Three years ago the Scott act was adopted by 4000 majority. The new Taschereau law which will go into effect in November abolishes the open bar, but permits the sale of alcoholic liquors in stores of the Government Liquor Commission, and beer and wines in the taverns, restaurants, clubs, etc., duly licensed by the commission. The clergy made no fight to retain the prohibition law.

Harvard Infantile Paralysis Commission Needs Funds.—The Harvard Infantile Paralysis Commission, which has conducted a clinic for crippled children since 1916, is soliciting contributions for continuation of its work. At present 1107 patients are receiving treatment under the direction of the commission. Of these 331 have been under treatment for five years. The value of the commission was shown in the outbreak of infantile paralysis in the summer of 1920, when it demonstrated that a large percentage of the children afflicted last summer have been saved from considerable deformity in comparison with those of the 1916 group. The cost of the work for one year is $25,000.

Dedication Exercises of Peking Union Medical College.—The formal dedication exercises of the Peking Union Medical College, which has been erected by the China Medical Board of the Rockefeller Foundation, were held on September 19. Ceremonies in connection with the dedication began on Thursday, the 15th, and included an international medical conference attended by government representatives and delegates from universities and other medical schools. The formal installation of Dr. Henry S. Houghton as Director of the College was one of the important events of the week. For the first time the Board of Trustees, composed of representatives of the Rockefeller Foundation and the six missionary societies which founded an earlier medical college in Peking, held one of its regular sessions there.

Lower East Side District Healthiest in New York.—A report recently made public by Dr. William H. Guilfoy, Registrar of Records of the New York City Health Department, shows that Sanitary District 26 has the lowest mortality in the city. This district consists of ten square blocks from Third to Ninth streets between Avenue A and Avenue B. The population of this district is 33,373.

or more than 3000 persons to a block. Here the mortality rate is 6.44 for each 1000 inhabitants, while the city's average mortality rate is 12.93 per 1000. The infant mortality rate in this district is 52 a 1000, and the infant mortality rate of the city as a whole is 85 per 1000. In commenting on these figures, Health Commissioner Dr. Royal S. Copeland says the people in this section have been accustomed to governmental control in the countries from which they came, and when they come here place themselves under the regulations of the Health Department, patronize baby health stations and follow the Board of Health teachings. He says it is a sad commentary on our citizenship when the children of well-to-do Americans are not as well cared for as those of the foreign born.

Drive for New Jewish Hospital.—The United Israel-Zion Hospital which is being erected on Tenth Avenue, between Forty-eighth and Forty-ninth streets, Brooklyn, is conducting a campaign to raise $100,000 toward the completion of its $1,000,000 building. A drive is also being planned to obtain funds for the erection of a nurses' home in connection with the new hospital.

Return of Polyclinic Hospital Demanded.—Five hundred graduate and student nurses of the Polyclinic Hospital in West Fiftieth Street, New York, have started to circulate a petition demanding the return of the hospital by the United States Public Health Service. The petition reads in part as follows:

> The continued occupancy of this hospital by the Government is unjust, un-American and akin to confiscation. The trustees, medical staff and women's auxiliary board and graduate nurses of the Polyclinic Hospital requests the citizens of New York, especially those who reside in or are engaged in business within the district allotted to the ambulance service of this hospital, to join with them in the demand that their property now unjustly held by the Treasury Department be restored to the owners and that the mayor and aldermen of New York City, our Senators and Representatives in Congress take such action as will enforce the immediate return of this great hospital to the service of the people of New York.

Commenting on the action of the Trustees of the Polyclinic Hospital, Surgeon General Hugh S. Cumming states that the Polyclinic Hospital is not particularly well suited to the care of ex-service men, and that the United States Public Health Service has been trying for a year to get a suitable institution in this city. This he thinks they will be able to do in a short time, and then they will also be able to move out of the Fox Hills Hospital. The Public Health Service has just taken over the large naval hospital at Las Animas, Col., which it will use for tuberculous ex-service men.

The Cincinnati Health Exposition.—An exposition that promises to be of great interest and practical value, is the Cincinnati Health Exposition, to be held in Music Hall, Cincinnati, Ohio, October 15 to 22. One of the main features of this exposition is Rural Sanitation Day. A program of special interest to farmers and their families has been prepared and many attractions of vital importance to those who live in rural communities will be displayed. A definite program for the safeguarding of the health of those who live where doctors and nurses are not available at a few minutes notice, as in cities, will be outlined, and special stress will be laid on the prevention and treatment of the diseases and ailments which frequently present a tremendous problem to those who live in rural communities. The exposition has received the endorsement of President Harding, Governor Harry L. Davis, of Ohio, and the mayors and health commissioners of cities throughout the whole country. Many health experts have accepted invitations to lecture on various health matters during the exposition. The program will be varied by showing motion pictures depicting the simplest methods of safeguarding the public health and interesting pageants prepared by members of local health expositions. The medical division of the Board of Health will have the complete equipment of a school physician's office with a doctor and nurse in attendance to examine children attending the exposition. The joint exhibit will consist of an *x*-ray room, private room, operating room, children's department, dietetic department, and handicraft department. Demonstrations of the work actually carried out in Cincinnati's hospitals will be given by some of the most prominent surgeons.

Public Health Institute Courses.—In response to a preliminary announcement of the Public Health Institute, which the Public Health Service had planned to hold in Washington next fall (but which has been postponed indefinitely), a large number of city and county health officers, physicians, nurses, and others replied indicating a definite intention or hope of attending. The Public Health Service has felt that it could not ignore this widespread interest in institute work, and after correspondence with the various State Boards of Health, has decided to hold a series of twenty-four institutes at various population centers throughout the country. It is expected that most of the well-known specialists announced for the two-weeks' institute in Washington will be on the faculties of two or more of the various local institutes. No tuition will be charged. The following are the cities where the Institute courses will be held: Hot Springs, Jacksonville, New Orleans, Columbia, S. C., Dallas, Birmingham, Memphis, Louisville, Indianapolis, Pittsburgh, Lansing, Chicago, Minneapolis, Los Angeles, San Francisco, Portland, Ore., Kansas City, Kans., Spokane, Newark, Helena, Albany, N. Y., Denver, A New England City, Washington, D. C. The Hot Springs, Ark., and Chicago institutes will deal only with problems of venereal disease control.

State Health Department Has New Films.—Three new motion picture films have recently been purchased by the State Department of Health and are now available to public health workers. The first one is a film on mouth hygiene and shows the necessity of caring for the teeth, the causes of decay and proper methods of cleansing the teeth. The second, "Saving the Eyes of Youth," deals with the prevention of blindness in newborn babies and emphasizes the need of precautionary measures. "Swat the Fly" is the name of the third film but does not fully describe it, for this film shows the anatomy and life history of the fly and depicts its peculiarities and many incidents in its life. Each of these films is in one reel and takes about twenty minutes to run and they are all of them of a nontechnical character and well adapted to general use. Besides these films the Department is co-

operating in the production of a film on water supply in the farm home. This is to be in two reels and shows how the rural resident, deprived of city facilities, may himself install a complete plumbing system in his home.

Failure to Report Cases of Venereal Disease.—The *Weekly Bulletin* of the New York City Department of Health for September 10, calls attention to the fact that the number of cases of venereal disease reported to the Health Department is so small that one is not justified in drawing any conclusions from the figures as to the prevalence of venereal diseases in the city. It is noted that a very small number of cases are reported by genitourinary specialists as a class. During the year 1920, the total number of venereal cases reported, from all sources, was 23,977, a decrease of 1142 cases, as compared with the total number reported in 1919. The principal cause of this difference is due to the falling off in the number of cases of gonorrhea reported in 1920. During this period the various hospitals and dispensaries reported 2572 cases of syphilis, as contrasted with 6096 cases reported by them during the preceding year.

Dr. Robert L. Moorhead has removed his office to 142 Joralemon Street, Brooklyn, N. Y.

Dr. Frederick W. McSorley, formerly Supervisor of Tuberculosis Hospitals, Clinics and Dispensaries in the New York State Department of Health, has been appointed Director of the Division of Tuberculosis, to succeed Dr. Malcolm F. Lent, resigned.

Gifts and Bequests.—By the will of the late Louis Mark of Philadelphia, the following bequests are made: Sinai Hospital, $3,000; Jewish Hospital, $2,000; Hebrew Sheltering Home, Hebrew Orphans' Home, Downtown Consumptives' Institute, Juvenile Aid Society, each $1,000.

By the will of the late Jennie M. Shoemaker of Philadelphia, one half of the residuary estate is bequeathed to the trustees of Jefferson Medical College as a memorial to her husband, the late Dr. John V. Shoemaker, to be used in assisting poor, deserving students of the college in paying their tuition and board, the amount payable to any one student not to exceed $300 annually.

Medical Society Elections. — THE AMERICAN ELECTROTHERAPEUTIC ASSOCIATION, at its annual meeting held in Washington, D. C., Sept. 7-10, 1921, elected the following officers for the ensuing year: *President*, Dr. Virgil C. Kinney, Wellsville, N. Y.; *Vice-presidents*, Dr. Christian M. Sampson, New Brighton, N. Y., Dr. Elmira C. Folkmar, Washington, D. C., Dr. Charles Reed Collina, Washington, D. C., Dr. Howard T. Plank, Chicago, and Dr. William T. Johnson, Philadelphia; *Treasurer*, Dr. Williard Travell, New York; *Secretary*, Dr. A. Berne Hirsch, New York; *Trustees*, Dr. Byron Sprague Price, New York, and Dr. Frederick H. Morse, Boston.

Obituary Notes.—Dr. RICHARD B. COUTANT of Tarrytown, N. Y., died after a long illness on September 13, at the age of seventy-six years. He was graduated from the College of Physicians and Surgeons, New York, in 1872. He was consulting physician to the State Hospital for Crippled and Deformed Children and chief of staff of the Tarrytown Hospital.

Dr. FRANKLIN PIERCE WARNER of Canandaigua, N. Y., a graduate of New York University Medical College in 1881, died on August 30, at the age of sixty-nine years.

Dr. SAMUEL T. LIPSITZ of St. Louis, Mo., a graduate of Washington University Medical College in 1906, died in a local hospital on September 2, at the age of thirty-six years. He was on the staffs of the Jewish and City Hospitals.

Dr. THEODORE A. MCGRAW of Detroit, Mich., one of the founders of the Detroit College of Medicine and for forty-three years head of the department of surgery, died on September 6, at the age of eighty-one years. He was a former president of the American Surgical Association.

Dr. STEPHEN COOPER AYRES of Cincinnati, Ohio, died on September 2, at the age of eighty-one years. He was graduated from the Medical College of Ohio, Cincinnati, in 1864. He served in the Civil War and at the end of the war had charge of the United States Barracks Hospital in New Orleans. Later he served on the staff of various Cincinnati hospitals.

Dr. JOHN MARKER, superintendent of the Eloise County (Mich.) Hospital, was killed in an automobile accident on September 2. He was graduated from the University of Michigan Medical College in 1890, and was fifty-nine years of age.

Dr. OSCAR A. KING of Lake Geneva, Wis., died on September 12, at the age of seventy years. He was graduated from Bellevue Hospital Medical College in 1878, and studied at the University of Vienna. He was for a time assistant physician in the Wisconsin State Hospital for the Insane, and since 1900 Vice-dean of the College of Physicians and Surgeons of the University of Illinois. In 1883 he founded a private sanatorium at Lake Geneva.

Correspondence.

THE MEDICAL REFEREE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The World War created many unique positions and titles and the Medical Referee was one of those born after this manner. The Civil Service Commission listed the "Referee" and also "Physician" under the examination as given by the board. Several have been sworn in and accepted under Civil Service rules and many good Referees are at work after special training, not under Civil Service. The work of the Referee in Washington, D. C., and elsewhere is now with the Veterans Bureau and it consists in examining the contents of folders covering individual cases and giving ratings on the various disabilities presented.

The idea prevails generally among the medical profession that the rating of a man's disability is a simple procedure. In a few cases it is, but in others it is not. In each case history, there may be as many as six physical examinations, by one or several doctors (often giving as many separate diagnoses), with 25 to 150 pages or reports from specialists, inspectors, buddies, hospitals, congressmen, and if an old case, a number of previous ratings, then one will scarcely appreciate the detail of which this work consists. In the rating of a disability the man's *previous principal occupation* must

be taken into earnest consideration and *if he is able to resume it or not*. For instance, if a pianist lost a finger in service, the disability is plain and he is rated accordingly; again any claimant with a clear history of service origin and straight diagnosis such as the loss of one leg or rheumatism following tonsillar infection in service, that is not a difficult matter to adjust.

When, however, a series of physical examinations are found in the folder with frequently conflicting surgical and medical diagnoses, the rating becomes more complicated and when to the above conditions are added the refusal of the claimant to accept hospital treatment (though strongly advised to do so) and specialists and hospital reports are attached with urgent requests from the Red Cross, American Legion, church societies, congressmen, etc., etc., the amount of labor and thought expended on each individual case is little appreciated by the various organizations and much less by the suffering claimant who awaits the award.

It was easily understood by the painstaking medical Referees in Washington, D. C., but not by the thousands of applicants why, on May 1, last, the new Director of the War Risk Bureau, Col. Charles R. Forbes, through the chief Medical Advisor, called for additional physicians from the various districts throughout the country. At this time over 60,000 cases were awaiting adjustment, the Bureau having become overwhelmed with work. It was only after two and one-half months that conditions became normal, each man receiving attention.

Under Col. Charles R. Forbes's far-sighted policy and direction, clean-up squads are operating throughout the country at present. These consist of examining physicians, a medical referee, clerks, etc., the idea being to reach every person who has a claim, investigate it, examine the individual, give a rating and immediate hospitalization if necessary, and also make a full report on every case. Many pathetic and worthy cases are thus discovered while other types are observed.

I have refrained from being led into discussion of the psychoses, hospitalizations, rehabilitation, vocational education, though these are closely linked up with the referee's work and wish to suggest a thought in closing to the medical examiner of claimants.

There is one thing most desirable from the medical referees point of view: It is that you examine carefully each case and visualize on paper your physical findings and particularly your impressions of the claimant in clear language. Keep in mind the referee can see the liability and the type of man only as you can describe it on your examination.

The lack of appreciation of the foregoing by the medical examiner has undoubtedly been the cause of much delay in the prompt settlement of claims.

E. C. CHAMBERLIN, M.D.

4 WEST EIGHTY-FOURTH STREET,
NEW YORK CITY.

Vitamines of Cooked Meat.—Briand concludes from a research that cooked meat contains little or no antineuritis vitamine, while the loss in other vitamine is less marked. The antineuritic component is not a loss outright as it merely passes into the cooking liquor. Even fresh meat contains but relatively little fat soluble vitamine and it is doubtful if cooking reduces this much.—*La Presse Médicale.*

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, September 1, 1921.

A Warning Against Extravagant Claims for the X-Ray Treatment of Cancer.—The Council of the British Association for the Advancement of Radiology and Physiotherapy have issued a statement to the effect that in view of the publicity that has been given to radiotherapy in the treatment of cancer by the publication of laudatory articles in the medical and lay press, and the extraordinary claims that have been put forward by the authorities of the West London Hospital, it seems advisable that a considered statement on the use of these agents should be made. The treatment referred to has not yet been thoroughly tested. It possesses great potential dangers, and may not prove as efficacious as the claims now made would suggest. In the nature of the case, however, no certainty can be arrived at for some years. The unwarranted laudation of this change in technique will probably lead to a reaction, and bring discredit upon *x*-ray treatment in general. The claim put forward by the Erlangen School is that by means of their special method it is possible to administer a dose of *x*-rays which will cure cancer in one application. The *Lancet*, in a leading article in its issue of July 2, commented in somewhat caustic but well-advised terms on these distinctly premature statements, concluding in these words, "We wish to say once more how much it is to be regretted that hasty opinions on medical matters should be given wide publicity. Such pronouncements, unless authoritatively traversed, could not fail to be harmful to the future of radiology, in that they raise hopes which are far from certain of realization. *X*-rays have already relieved suffering and prolonged active life in thousands of cancer victims. They have even effected a few apparent cures; and their value in helping to prevent return after operation is now generally recognized. It would, therefore, be neither more nor less than a calamity if public disappointment resulting from unfulfilled promises were to bring discredit on radiation therapy, which is in reality a powerful agent in the warfare against disease." This expression of opinion is very much to the point. A great many of the reputed cancer cures and most of the widely heralded consumption cures hail from Germany. Of course, *x*-rays have proved themselves of great value, and the merit of the much-discussed Erlangen apparatus consists mainly of its greater penetrating powers. However, that is no valid reason why preposterous assertions should be made concerning its curative effects, bringing ofttimes calamitous results on the sufferers and to the great detriment of a means of treatment which, judiciously employed, promises to become of the greatest service to diseased humanity.

Lessons of the Census.—In the decade just gone by the population of Great Britain has increased by 1,936,134, a fair showing when the happenings of the past few years are taken into consideration. The increase is about half of what it was in the previous ten years' period. The slackening of the growth of population is due mainly to the

war, for in addition to the number of men killed, 560,000, of course, many fewer children were born, owing to the absence of men at the front. Other causes of this diminished increase of population were perhaps the severe epidemic of influenza and the slightly heavier flow of emigration during the decade, although during the war emigration was practically suspended. The population of Great Britain at the present time is 42,767,530, compared with a total in 1911 of 40,831,396. For the whole of Great Britain the increase was at the rate of 4.7 per cent., the lowest rate of increase yet recorded. In the preceding intercensal period the increase was 10.4 per cent., and this was lower than the rate in any previous decade. The excess of females over males in Great Britain is close upon 2,000,000. While males increased in number by 676,000, the increase in females was over 1,250,000, and the proportion of females to males in Great Britain rose from 1,066 in 1911 to 1,093 in 1921. Thus one of the direct legacies of the war, as demonstrated by the British census returns just published, is the increased preponderance of females over males. The influence of war conditions on the birth of boys appears to have received further confirmation by the facts revealed by the census. Since the first quarter of 1915 the ratio of male to female births in Great Britain has been steadily above the average. German authorities, and Dusing in particular, stated some time ago that the accentuation of the excess in war time was a well-known and undoubted fact. Cold water has been thrown on this theory by others; but it remains true that, so far as this country is concerned, an abnormal increase of boy over girl babies has, with a certain amount of fluctuation, continued since 1915 until the present time. The ratio in the past quarter being 1,057 births of boys to every thousand births of girls. In this connection there is another interesting fact worthy of mention, that England has long been remarkable for the low excess of male over female births, not only as compared with the countries of the continent of Europe, but also with the other parts of the United Kingdom. It must also be borne in mind that, while more boys than girls are born, female infants are more tenacious of life than males. Yet if the increase in the ratio of male births continues, it should, in time, aid in counteracting the present surplus of females. Sir Bernard Malet, the late Registrar General, in a recent interview deplored the fact that, owing to the inclusion of new questions, such a valuable feature as the fertility inquiry—that is, the number of existing marriages and the number of children born to them in different social classes—had to be omitted. This was inserted for the first time in 1911, and, as Malet said, it is to be hoped that the results of that inquiry, which was delayed by the war, will not be lost to statistical science and that the expert comment on the figures to which Doctor Stevenson is known to have devoted much labor will see the light in due time. It is pointed out that it is the first investigation of the problem which has been made on a large scale.

The Size of a "Panel Doctor's" Practice.—The Minister of Health was asked the other day in the House of Commons what was the maximum number of patients a doctor might have on his panel. Sir A. Mond, the Minister of Health, in his reply said the limit of the number of insured persons whom an insurance practitioner may have on his list is determined by a scheme made for each area by the Insurance Committee and the Panel Committee jointly, and the extent to which the limit may be increased where the doctor engages one or more permanent assistants is determined by the Insurance Committee, which is required to have regard to the particular circumstances of the doctor's practice. No doctor working single-handed may have more than 3,000 persons on his list; the maximum has been fixed in a large number of areas at 2,000 to 2,500, and the average number per doctor is approximately 1,000.

North-East London Postgraduate College.—A special postgraduate course will be held at the Prince of Wales' General Hospital, Tottenham, London, N., from Sept. 26 to Oct. 8. It will include practical demonstration on clinical and laboratory methods each morning, demonstrations on groups of selected cases, general hospital work, and a clinical lecture each afternoon. Practical demonstrations will also be given in associated special hospitals. A good deal of progress has been made lately in Great Britain in arrangements for postgraduate teaching and training, but, so far as London is concerned, the big scheme for making of that city a world's postgraduate center, initiated and fostered by Sir John Macalister and Sir Arbuthnot Lane, does not advance so rapidly as might be desired.

LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, Sept. 1, 1921.

Increase of Population in France.—Statistics relating to the growth of the population of France show that last year the excess of births over deaths was 159,790, as against 58,914 in 1913, while the number of marriages has doubled. It is the first time since the war that statistics have been available for the whole of France, including the three departments of Alsace-Lorraine. The births were 834,411 last year, compared with 790,355 in 1913—an increase of 44,056. The deaths were 674,621, against 731,441 in 1913—a decrease of 56,820. The marriages numbered 623,869 last year, against 302,036 in 1913.

Smallpox.—For many years Switzerland has not been visited by an epidemic of smallpox, but this year there have been two outbreaks, as usual imported from Germany. Bâle and Zurich were the foci of the epidemics. That of Bâle was imported from Frankfort, the disease presenting its customary characters, viz.: serious, with some deaths, in the non-vaccinated, much lighter in vaccinated subjects even when the last vaccination dated back from twenty to forty years. Immediate isolation of the patients and members of their household, vaccination of persons dwelling in the infected houses and those having come in contact with "suspects" at once controlled the

spread of the epidemic. The source of the Zurich-Oerlikon epidemic has not as yet been discovered; it offered quite a different aspect from the Bâle episode. Among the 120 persons infected there were hardly half a dozen serious cases, although the majority of the patients had never been vaccinated or were old people who had been vaccinated from thirty to sixty years previously. In many the disease was mild and atypical. The cornea reaction or the cuti-reaction had to be carried out in order to certify the diagnosis. For this reason it is obvious why the search for the source of the epidemic has so far led to no results, but it was probably "made in Germany." Switzerland is more than sufficiently supplied with vaccine furnished by the Vaccine Institute at Berne and the Vaccinogenous Institute at Lausanne. The superior quality of the vaccine furnished by either of these establishments is well known outside of Switzerland, so that in this respect the profession has everything to be desired.

Regulation of the Sale of Milk.—The Swiss Federal Council has, among other laws respecting the sale of foodstuffs, published the following on the regulation of the sale of milk: "Whoever wishes to place on the market a milk having a special denomination, such as milk for infants, invalids, etc., must make application to the local sanitary authorities. Authorization can only be accorded to persons, companies, and manufacturers who can give sufficient guarantee that they are so placed that they can furnish a milk possessing the special qualities claimed for it. When a manufacturer does not conform to the articles regulating the manufacture of specially prepared milks or refuses to introduce those improvements in its manufacture that may be required of him, the authorization above given may be withdrawn at any time and for such withdrawal no action for damages can be brought in the courts of law."

Transmission of Foot-and-Mouth Disease to Man.—At a recent meeting of the Academy of Science of Paris a highly important paper by Le Bailly of Caen, on the transmission of foot-and-mouth disease from cattle to man was read. For over half a century this transmission has been admitted to take place by the milk of infected animals and numerous facts seemed to have demonstrated the frequency of this contagion. Le Bailly has not succeeded in producing foot-and-mouth disease by inoculating healthy animals with the saliva obtained from a child and two adults suffering from stomatitis due to aphhæ epizooticæ. He also attempted, without success, to contaminate human beings with foot-and-mouth disease by inoculating three persons with from two to eight cubic centimeters of virulent blood-serum. These results are interesting but rather unexpected and should be submitted to experimental control.

Syphilitic Mongolism.—Lhermitte performed an autopsy on a "Mongolian" child dead of some acute enteric disorder. The lesions were those of congenital syphilis, which condition had also been recognized during life. There were alterations in the cerebrum (corpus callosum), spinal marrow, liver, kidneys, thyroid, and adrenals. No light was thrown on the nature of essential mongolism.—*Gazette des Hôpitaux.*

2. The Reduction of Hypertension in an Unusually Difficult Case by Means of a "Salt-Free" Diet.—M. J. Konikow and Millard Smith report this case of hypertension in a woman of 54 years, upon whom careful observations were made over a period of 115 days. A salt-free diet, as outlined by Dr. F. M. Allen, was employed, and chemical examinations of the blood and urine made at suitable intervals. Their experience with this case supports the view that lessened intake of salt is a lowering factor in hypertension cases. This case was unusually difficult, little benefit being noted from the diet until almost the end of the experiment, which had covered many weeks. As a rule hypertension cases secure relief from their distressing symptoms within a short period after the introduction of the "salt-free" diet, and with this relief there is a reduction of hypertension. The fact that this patient was so slow to respond to the diet emphasizes the need for prolonged treatment in some cases before results can be secured. Another point to be noted is that the diet must be carefully followed with urine examinations to be sure the patient is keeping the salt intake at a very minimum. It is desirable to keep the salt excretion below 1.0 gram of sodium chloride, and better below 0.5 of a gram. Though this was not possible in the case reported, the hypertension was definitely lowered and an improvement in symptoms was noted. The writers agree with Allen that this dietetic treatment is only palliative and that it does not reach the real cause of faulty metabolism of chloride. In this patient it was possible that there was an endocrine basis for the hypertension, as she had outspoken symptoms of disturbed function of the thyroid gland, induced possibly by the early removal of the ovaries. The therapy in such cases should perhaps not be limited to a salt-free diet alone, but should be followed by organotherapy.

4. Remarks on the Differential Diagnosis between Tuberculosis and Certain Other Chronic Pulmonary Infections with Special Reference to the Late Effects of Gas and Influenza.—John B. Hawes, 2nd, summarizes the important points in differentiating tuberculosis from the late effects of influenza as follows: (1) There is usually a train of symptoms definitely related to and following an attack of influenza. (2) There are marked constitutional symptoms, such as shortness of breath, weakness, lack of strength and energy, and (3) in contrast to this, usually a normal temperature and pulse, blood and blood pressure, and but little loss of weight. (4) There usually is some cough and sputum which is often bloody. (5) There is rarely any evidence of consolidation in the lungs, but about everything else may be present, especially at the bases. The pathology in the lungs of the men who were gassed consists of a diffuse fibrosis not localized at the apex, base, or hilus, but found in any region in the lung. Fever, rapid pulse, loss of weight, anemia, and other symptoms of tuberculosis are conspicuous by their absence. In differentiating the effects of gassing from tuberculosis the points that it is important to remember are as follows: (1) Do not take it for granted that a given process is tuberculous even with a suggestive *x*-ray. (2) Do not do the reverse. (3) A general appearance of robust health with marked symptoms is against tuberculosis. (4) Remember that the lung complications resulting from gas are usually found at the base and not at the apices; (5) and that the usual signs found are those of a thickened pleura and often a localized bronchitis, although in many instances little or nothing is found in the lungs. (6) Bear in mind that following gas there is apt to be a marked increase

in nervous symptoms of every kind. (7) Do not take for granted that those men who have been gassed are *not sick* and do not need treatment. (8) Treat the man who has been gassed and not his lungs. In the diagnosis of primary carcinoma at the root of the lung, the writer has been impressed by three points, namely, that the fact that the patient is not older than 30-35 years does not mean that cancer is not present; that almost every sign and symptom suggestive of pulmonary tuberculosis may be present, and that a negative *x*-ray, as far as cancer is concerned, is not necessarily conclusive evidence against a new growth, at least when the disease is in its early stages. The gradual onset of symptoms is a point favoring the diagnosis of new growth.

3. The Action of Various Salts and Other Substances on the Liver After Their Introduction into the Duodenum.—Max Einhorn presents further studies on the action of salts other than magnesium sulphate on the liver after their introduction into the duodenum. He used sodium sulphate, sodium citrate, bicarbonate of sodium, chloride of sodium, calomel, mercurochrome, and other substances, the method used being identical with that described in former papers. From these experiments it is shown, as in a former paper, that Lyon's assumption of the different sources of bile, as judged by the color, does not seem to be correct. In regard to the question as to what are the best conditions for the examination of the bile in gallbladder lesions, he states that inasmuch as the magnesium sulphate and other liver stimulants increase the flow of bile from the liver and drive it, so to say, quickly and directly into the duodenum, there will be after these substances a bile product from the liver direct containing very little if any bile from the gallbladder. In the fasting condition, and without any previous stimulation, the aspiration succeeds in obtaining what little bile there is in the duodenum from the liver and gallbladder, or there seems to be more chance for the appearance of some gallbladder bile when the flow of liver bile is not extensive. In practising bile examinations in the fasting state of the patient, for the past ten years or so, he has found this to be the case. Diagnostically, then, we can find many more valuable hints regarding gallbladder lesions from the examination of the natural fasting bile than from the bile obtained after stimulation by magnesium sulphate. In cases of jaundice, however, in which no bile is found in the fasting state, a liver stimulant may be injected into the duodenum, in order to ascertain whether the increased flow of bile from the liver is still able to push through some of its products into the duodenum. In fact, in a number of such cases of chronic jaundice with no bile in the duodenum while fasting, the magnesium sulphate caused the appearance of some bile after a short time, thus showing that the common duct occlusion was not complete. In these cases the magnesium sulphate or peptone or glucose test is of diagnostic aid.

5. Personal Experience with Nonsurgical Biliary Drainage.—Julius Friedenwald and Theodore H. Morrison have employed the Lyon method of diagnosis and biliary drainage, with slight modifications, in 315 observations. They find the technic simple. In many instances it has been carried out by nurses and later on by the patients themselves. In this series 120 cases were due to biliary stasis, the bile being thick and tarry and requiring many attempts before the gallbladder could be thoroughly cleared. It is also infected with many microorganisms. With daily treatments, often extending over many weeks, such cases can be greatly benefited, the bile assuming after a time a more normal appearance, the microorganisms gradually decreasing in numbers, and the patient then presenting a marked improvement in his condition. It is quite probable that in many of these cases the formation of gallstones can be prevented by this form of treatment. In a large series of cases grouped under the term biliousness, a rapid change in the appearance of the patient and an improvement in digestion and constipation, with complete relief from acute attacks of sick headache and migraine, has followed the institution of this form of biliary drainage. The authors conclude as follows: (1) The method of biliary drainage, as instituted by Lyon, furnishes a valuable aid in the diagnosis of gallbladder affection. It is particularly valuable in that it enables us to diagnose these conditions early before evidences of complications have manifested themselves. (2) It presents an important means of determining the presence of focal infection in the gallbladder, a condition which may be of the greatest therapeutic and diagnostic value in obscure conditions. (3) While this method of treatment is still in its infancy, and it is as yet too new to draw conclusions regarding its end results, there can be no question that it furnishes a means of affording definite relief in certain biliary affections for which hitherto radical measures have been required. It is an extremely valuable aid in treatment of catarrhal jaundice, biliary stasis, and gallbladder infections, and is helpful in relieving the infection which may still remain following gallbladder operations. The writers also describe a bacteriological study carried out by Dr. Charles E. Simon showing clearly that bacterial infections of the gallbladder are much more common than has hitherto been supposed, and that infections with pyogenic cocci are much more frequent than bacillary infections. It would seem that no search for foci of infection can hereafter be regarded as complete which does not include an examination of the bile.

2. Unrecognized Infections in Production of Carriers of Pathogenic Organisms.—Charles F. Craig emphasizes the enormous importance of the unrecognized carrier in the transmission of bacterial and protozoal disease. He discusses two types of carriers, namely, "convalescent carriers" and "contact carriers," the latter being the most important source of endemic and epidemic infections. The idea that contact carriers have never suffered from the diseases due to the parasites they carry is erroneous; a very considerable proportion of them have presented, at one time or another, symptoms which were undoubtedly due to the parasite

they carry. This type of carriers originates from unrecognized and atypical cases of contagious or infectious disease. This fact should lead the physician to a more careful consideration of apparently trivial symptoms and to a greater utilization of laboratory aids in the diagnosis of their cause. Most of these cases would be recognized if physicians were on the outlook for them. After calling attention to the large number of missed cases of diphtheria and typhoid fever, Craig discusses unrecognized malarial infections, and states that about 50 per cent. of those infected with malaria develop gametes and thus become carriers. Inquiry into the history of malaria carriers almost invariably shows that they have at some time had mild symptoms which, while not those of the typical malarial paroxysm, would have been regarded as suspicious by the trained physician. Early recognition and treatment of malaria prevents the development of gametes. Another infection which physicians through the United States should be on the lookout for is amebiasis. On the basis of the percentage of infections with *Endamœba histolytica* among troops on the western front during the war, there must have been returned to this country at least 500,000 men who were carriers of the cause of amebic dysentery and potential agents for scattering the infection throughout the United States. Most of these carriers have had symptoms due to their infection, though a history of dysentery is denied. However, if questioned with reference to slight attacks of diarrhea, generally lasting only a few hours, the vast majority will admit the occurrence of this symptom, stating that these attacks frequently occur at night and subside after the passage of one or more profuse stools accompanied by more or less abdominal pain. These carriers also suffer from intestinal indigestion, a feeling of malaise, and periods of loss of weight, especially in hot weather. Though these patients frequently consult a physician for the relief of these symptoms, it is but rarely that amebic infection is suspected and a microscopic examination of the feces requested. The medical profession should realize that amebic diarrhea is very common in this country and is becoming more so.

4. Diphtheria Prevention Work in the Public Schools of New York City.—Abraham Zingher. (See MEDICAL RECORD, July 2, 1921, c. 1.)

10. An Etiological Factor in Angioneurotic Edema.—Frederick Myles Turnbull presents a preliminary report in which he describes two cases of angioneurotic edema in which the condition was entirely relieved after radical sinus operation. In both instances the sinuses not only contained pus, but there was marked polypoid degeneration of the lining membrane. He calls attention to a great similarity between angioneurotic edema and certain anaphylactic reactions. We know that asthma and certain bronchitic conditions may be merely anaphylactic reactions, and likewise that sinus infections and nasal polyps may result in a respiratory picture very similar to the ordinary anaphylactic reactions. It is quite conceivable, and these cases indicate very strongly that there may exist an etiological factor in these chronic nasal sinus infections, with the accompanying polypoid change, which may cast much light on anaphylactic manifestations in general. Certain experimental work is being conducted along this line.

13. Blood Sugar and Basal Metabolism Findings in Chronic Pulmonary Tuberculosis and Hyperthroidism.—R. A. McBrayer has studied the basal metabolism of 23 incipient, 17 moderately advanced, and four far advanced cases of pulmonary tuberculosis, making 100 determinations. In 59 per cent., three cases of which are suspicious hyperthyroids, the basal metabolism was increased over 10 per cent.; in 36 per cent., one of which was definitely hyperthyroid, there was a normal basal metabolic rate, and in 5 per cent. there was a decreased metabolic rate. An analysis of the blood sugar curve in 74 tuberculous cases showed the blood sugar increased in 58 per cent., normal in 27 per cent., and decreased in 15 per cent. Remembering that hyperthyroidism consistently shows both an increased basal metabolic rate and an increased blood sugar, it is impossible to draw from this work any other conclusion than that the determinations of basal metabolic rate and blood sugar are of no practical value in the differential diagnosis of pulmonary tuberculosis and hyperthyroidism.

1. An Experimental Study of Prophylactic Inoculation in Typhus Fever.—A. Kusama has conducted further experiments with the invisible virus of typhus fever, using the Macacus monkey. It has been observed that the incubation period differs according to the site of inoculation of the virus, the virulence, and the quantity of virus or blood. The incubation period is shortest when the virus is inoculated into a vein, or is very strong, or is given in large quantity. The incubation period is directly proportional to the pyrexial period. If the symptoms develop after a longer period of incubation, the days of the disease are fewer, and vice versa. As to the amount of dosage, it has been found that monkeys which received injections, either hypodermic or intravenous, of one-tenth or less of the minimal morbid dose of virus, had a febrile attack. It was found that the same degree of immunization was possible, obtained by the use of very different doses (1/10 to 1 100,000 of the minimal morbid dose). The outstanding fact presented is that the use of a minute quantity of typhus virus, not attenuated by a special method, can harmlessly confer upon an animal a prophylactic power against the virus. The practical application of this fact must, however, be postponed until the virulence of the prevailing virus, the individual differences in susceptibility, and the degree of immunization are fully established. These problems must be settled by future research.

5. Some Observations on Basal Metabolism in Menstruation.—Marion O. B. Wiltshire reports a series of experiments comparing the physiological processes in the menstrual and intermenstrual periods. The points chosen for determination were: (1) The basal metabolic rate of normal women during menstruation, and between the menstrual periods. (2) the cost to the organism, at these times, of a definite piece of work, and (3) the rate of recovery from that work. Observations were made on five subjects, in whom it was found that the intermenstrual values varied considerably in different subjects, although the mean value, 37.2, agrees with that given by Benedict as an average value for women. The variations during the different phases of the sexual cycle are so small that they cannot be regarded as showing any marked effect due to menstruation; the fluctuations which normally occur are often greater than these variations. In regard to the second and third points investigated the results seem to indicate that the cost of work and the rate of recovery from work are the same during the menstrual and intermenstrual periods. In both cases there is a sharp rise in the carbon dioxide output and the oxygen intake during exercise, followed by a gradual return to the resting value when work ceases.

2. Some Contrasts in the Effects of X-Rays and Radium Upon Blood Cells.—Sidney Russ states that a study of the effects of *x*-rays upon the circulating leucocytes of the rat has shown that for a certain measured dose of *x*-rays the effects upon the lymphocytes are regular and can be repeated, but the polynuclear leucocytes show quite irregular changes, for an increase or a decrease in their numbers may occur as a result of the exposures. Observations as to the effect of exposures on man to rather large quantities of gamma radiation were made in thirty-one cases. A reduction in the number of circulating lymphocytes was observed in twenty, and increase in five, and no change in six. The figures for the polynuclear cells for the same thirty-one cases showed that an increase, a decrease, or no change in their numbers was of very nearly the same probability. These subjects were not normal and a septic condition was the rule rather than the exception. Both the experimental and the observational data show that both *x*-rays and gamma rays may be expected to cause lymphocytes to disappear from the circulation. Changes in the red blood cells have also occurred after a single gamma ray exposure; they are not of a pronounced character, however, unless the radiation is very prolonged.

5. The Value of Radiation in Leucemia.—James Metcalfe says the chief point to be determined in connection with the treatment of pathological conditions in which the blood elements are among those chiefly attacked is whether the mobile elements absorb more rays with extremely high penetration than they do those of more moderate power. This is a matter which has not been settled and which requires most careful observation. The results of his experience in regard to the effect of radiations on the blood are: (1) That they produce remarkable improvement in the blood count and general health, and reduce the splenic enlargement and other hyperplastic tissues; and (2) that they are especially useful in some leucemias, splenic anemia, and Banti's disease. The earlier improvement is frequently not maintained; but there is great hope that with improved technique this will prove feasible. Radiation is certainly of no use in secondary anemias, and in the writer's opinion it is not useful in pernicious anemia. In connection with *x*-ray workers we should take into consideration the facts that, if healthy, they are much less susceptible to radiations then those of poor physique; and that the bad effects produced by exposure to radiations are much diminished by working in well ventilated rooms; by thorough protection of all apparatus by lead covering; by limited hours of work; by drinking a good deal of fluid (water or light lemonade) during the day; by being out in the fresh air as much as possible when not working.

9. Glycosuria of Malarial Origin.—Aldo Castellani and J. Graham Willmore record two cases in which glycosuria followed malarial attacks. The observations made in these cases tends to show that there is a form of glycosuria of malarial origin, and that the condition may at times, as in one of these cases, become so severe as to simulate true diabetes, the patient losing flesh, becoming very weak, complaining of thirst and hunger, and passing a large amount of saccharine urine. The glycosuria in these two cases was cured by the administration of quinine in full doses without any dietetic treatment.

4. Sugar Tolerance Curve in Gastrointestinal Carcinoma.—Henry M. Feinblatt has made observations in regard to the sugar tolerance test in carcinoma which confirm the work of Rhodenberg and Friedenwald. The technique of the test consisted in giving the patient 100 grams of glucose in black coffee after a night's fast. Venous puncture was made five minutes before giving the sugar, 45 minutes after ingestion, and again two hours after the intake. In each instance 5 c.c. of blood was withdrawn into a tube containing a few crystals of oxylate, and then promptly analyzed according to Folin's new microchemical method. Using this technique, sugar tolerance tests were made on 56 patients, from which it is concluded (1) that lowered sugar tolerance may be present in many diseases other than gastrointestinal carcinoma. These generally do not give the clinical symptoms or physical signs of carcinoma and may easily be ruled out. The sugar tolerance test is of distinct value as a means of differential diagnosis between carcinoma and other gastrointestinal diseases. The patients having carcinoma of the stomach or alimentary tract invariably showed hyperglycemia.

1. Pleurisy.—W. Hale-White calls attention to pains due to other causes that may be attributed to pleurisy. Such pains are those due to fibrosities in the back of the pectoralis major and neuralgic pains, both of which may be relieved by a liniment made of equal parts of menthol and chloroform to double the quantity of olive oil. Tubercle of the ribs, gumma of the ribs, and growth in the ribs have been mistaken for pleurisy. Not all pleuritic rubs are heard at inspiration and expiration, as the books tell us. There is no golden rule for telling one. Diaphragmatic pleurisy is difficult to recognize. If there is any pain, it is low down, usually somewhere about the tenth rib. Next you can often observe that the patient does not move his diaphragm properly. When he inspires the diaphragm does not descend on the side of the pleurisy, with the result that at the end of deep inspiration, the other side of the chest expands and the abdominal muscles come out, and it is easy to notice the drawing in of the ribs on the side of the pleurisy. Very often this evidence is not present, but if you suspect it, you will be surprised how often your suspicions are confirmed by noticing a rub low down. Another position of pleurisy difficult of detection is when it occurs between the perieardium and the lung. A common way to differentiate an exocardial murmur from an endocardial is to have the patient hold his breath, when you will not hear the rub if it is caused by inspiration and expiration. With regard to the treatment of pleurisy, there are two things to bear in mind. If it is a dry pleurisy you want to get the visceral and parietal pleura to adhere; therefore, you strap the chest. If there is fluid, but not sufficient in amount to make you wish to take it out, it is most likely to be absorbed if the patient is opening out his lung and his lymphatic spaces; therefore, if there is fluid do not strap the chest. Perhaps 75 per cent. of all serous effusions in the pleural cavity are tuberculosis. Medical men do not warn the patients enough that simple pleuritic effusion is most often tuberculosis. It is always worth while to see whether the fluid you remove is albuminous or not. All ordinary pleuritic effusion is albuminous, but hydatid fluid is not. Many physicians do not estimate enough the value of the skodiac resonance in pleural effusion. It is an extraordinarily valuable sign, quite impossible to mistake. Depression of the diaphragm is sometimes given as a sign of fluid; that is exeeedingly rare. If blood-stained fluid is caused by a growth, do not aspirate it, as the sudden release of pressure may cause further hemorrhage. It is a striking fact that the frequency of empyema has increased in recent years. In the presence of a continuing high temperature in pneumonia one should not comfort himself with the idea that he has a case of delayed resolution until he has definitely put out of court the possibility of empyema. There is no doubt whatever that a patient can get perfectly well if an empyema is coughed up. The writer has seen thirty such cases. As a rule, however, it is

wrong to leave the empyema to be coughed up. The *x*-rays are of very little use in the location of empyemata. A blood count is of much help in the diagnosis. If you cannot find an empyema and yet from the signs and symptoms think there is a fair probability that an empyema is there, don't go needling to find it between the pericardium and pleura; call a surgeon and let him open the chest freely and look for the empyema, find it, and drain it. When fluid has been evacuated get the lung to work again as quickly as possible.

Inoperable Cancer of the Stomach Treated with Electroselenium.—Blumenthal-Jacquet reports the following case: The diagnosis of cancer of the lesser curvature was made by the ordinary resources with the aid of biopsy in connection with attempted operation. Patient was a woman of 52 who had never had any illness, up to 1913, when she began to complain of epigastric pain two hours after meals with slow and painful digestion. There was no vomiting. This state of affairs had continued unchanged for 5 years, when the woman began to lose flesh rapidly and show profound anemia. Jaundice and hematemesis then supervened. A biopsy was made of some tissue in the vomitus and adenocarcinomatous tissue was recognizable. The bowel discharges were melanic. Deep palpation revealed a hard tumor of the lesser curvature. Operation was at once begun and a growth the size of a pigeon's egg was seen high up on the lesser curvature. The regional lymphnodes were enlarged and there were numerous adhesions with probable secondary implication of the liver. It was, therefore, decided to abandon the intervention. The patient returned home after having passed through a postoperative pneumonia. The author did not give up the case, but obtained from Holland at much trouble a quantity of electroselenium (it should be stated that the author is a Belgian and that this episode occurred before the armistice). A series of nine intravenous injections was practised at intervals of 2 to 4 days. The first was followed by a typical colloidal shock. At the close of the period the subject was able to take nourishment and ate practically everything, although she complained of the postprandial pain. After a second series of injections the latter symptom also disappeared. The patient did well, until, in 1919, there was a suggestion of recurrence, which led to a third series of injections, with a fourth in 1920 and a fifth later in the same year. Invariably a course of injections was at once followed by improvement. The patient is 66 pounds heavier than at the time of the operation. In November, 1920, after her last injections, she was presented before the Brabant Medical Society. She appeared in the best of health, and an *x*-ray showed that the tumor had been replaced by a double notch in the curvature. The case is considered most remarkable in view of the inoperability and presence of metastases and cachexia, to say nothing of the nature of the remedy, which in this one case has at least duplicated the best results of radiation. In case any reader would like to duplicate the treatment he is advised to make the first injection intramuscular to avoid the severe reaction, which, as the author soon learned, was not essential to the cure. The colloidal selenium should be mixed with an equal part of saline infusion or distilled water. The intravenous injections are to be made very slowly. That the selenium had any specific action may perhaps be doubted, as the author apparently found colloidal gold of the same value, although he is not explicit on this point and may refer to laboratory experiments made after the operation. The author believes that electroselenium and radium used in concert might give better results than any thus far obtained.

Cure of Suppurating Typhoid Spondylitis by Autovaccination.—Bureau and Marchand refer to the first description of typhoid spine by Gibney of New York. Osler was an early contributor to the literature of this subject. But at this period the nature of the process was unknown and it was not regarded as a specific lesion due to Eberth's bacillus, but rather as a postinfectious neurosis. Suppurative cases were originally so rare that for many years the affection was looked on as "dry." In 1919 Weil reported a suppurative case cured by autovaccination; and the authors have recently duplicated this success. Their patient was a woman of 47 who went through a seven weeks' typhoid fever in 1913. Among her symptoms were violent pains in the loins. Convalescence was tedious, backache being present off and on. After recovery there were pains in the loins, sacrum and right hip, without impairment of the gait. These became aggravated and at last patient took to bed. The pains had from the first been worse at night. The focus seemed to be the region of the third-fourth lumbar vertebrae, and they were radiated in all directions downward. The condition became very complicated, with fever and great disturbance of general health, in part explained by the formation of pus which pointed at the right groin. During several years there was a total of six of these abscesses. The pus contained Eberth's bacillus and a trial of autovaccination led to complete recovery. The exact period of pus formation was seventeen months after the fever. The authors suggest the use of a stock vaccine in the ordinary nonsuppurating case of typhoid spine.

American School Diet in Austria.—Von Pirquet, or Pirquet as he now signs himself, relates the visit of Dr. Alonzo Taylor to Vienna in 1919 as the representative of Herbert Hoover in the interest of feeding the Austrian children. Collaborating with Taylor were the author, as the representative of Austria, and several other Americans. Assisting Pirquet were Nobel and Mayerhofer, recognized experts in dietetics. Vienna and the provinces were alike included in the movement. It was intended to give out daily from 60,000 to 400,000 meals, beginning with the low figure, with the high one as objective. Hoover controlled $33,000,000 to feed the suffering children of the whole of Europe, and the headquarters for Middle Europe were in London. America furnished food only and the problem of distribution and preparation was entirely up to the governments, central and local, of the countries benefited. The provinces paid for freight and preparation. The cost of the entire meal when served was about 1 kronen, equal to from 3 to 6 mills of United States money, at the current rates of exchange; but during the feeding period further depreciation made the figure 2 kronen per meal. The cost of the food alone was six cents a meal, which with the overhead made the total about 6.5 cents. The fact seems to have been established that ignorance and indifference on the part of parents, not less than food scarcity, were responsible for the state of undernourishment which prevailed throughout the Austrian child population.

The "Second Wind" of Runners.—This term originated in England many years ago to denote the primary shortness of breath on effort which is followed soon after by easy breathing without any intermission of effort. To explain the phenomenon there are only theories. Chaillé-Bert and two others who have studied the behavior of runners on the revolving carpet discard all theories hitherto advanced and see only a process of adaptation of mechanism to effort in which with labor constant the rate of exchanges of gas is lowered.—*Gazette des Hôpitaux.*

Coming French Congresses at Strasbourg.—Next October will see the holding of three medical congresses at the metropolis of French Alsace-Lorraine. These are respectively the Surgical, Urological, and Orthopedic. Professor Boeckel, the veteran surgeon of that city, will preside over the Surgical Congress. The grand questions for discussion comprise the treatment of epilepsy following cranial injuries, serum and vaccine treatment of osteo-arthrites, analgesia in urinary surgery, bloodless treatment of congenital dislocation of the hip, arthrodesis of the foot, and operative treatment of ankyloses of the knee.—*La Presse Médicale.*

Book Reviews.

A Primer for Diabetic Patients. A brief outline the Principles of Diabetic Treatment; Sample Menus, Recipes and Food Tables. By Russell M. Wilder, Ph.D., M.D.; Mary A. Foley, Dietician; Daisy Ellithorpe, Dietician, the Mayo Clinic. Philadelphia and London: W. B. Saunders Co., 1921.

The authors acknowledge free use of Joslin's "Diabetic Manual." There are sections on the Purpose of Diet, Measures and Weights, Food as Energy, the Urine, with special reference to sugar and diacetic acid, Composition of Foods, Dietary Treatment of Diabetics, Treatment of Impending Coma, Menus and Recipes and Food Values. The number of pages of this 12mo volume is 76.

On Diseases of the Lungs and Pleuræ. Including Tuberculosis and Mediastinal Growths. By Sir R. Douglas Powell, Bart., R.C.V.O., M.D. Lond., F.R.C.P., Hon. D.Sc. Oxon; M.D. Dublin; F.R.C.P.I., LL.D. Aberd. and Birm.; Physician in Ordinary to H.M. the King; Consul. Phys. and Emeritus Lecturer on Medicine to the Middlesex Hospital; and P. Horton-Smith Hartley, C.V.O., M.A., M.D. Cantab., F.R.C.P., Late Fellow of St. John's College, Cambridge; Physician with Charge of Out-Patients to St. Bartholomew's Hospital. Sixth Edition, 1921; pp. 798. Price $10. Philadelphia: P. Blakiston Son & Co.

The comprehensive heading of this book of nearly 800 pages is evidence of the vastness of the subjects covered, and the titles following the names of the authors may be taken as a guarantee of the value of the publication. To give a detailed review of the 54 chapters would require more space than any weekly medical journal could afford. The book is virtually a review of all that is known up to date of the anatomy, physiology, pathology, bacteriology, physical diagnosis and treatment of diseases of the chest, including not only, as the title indicates, tuberculosis and mediastinal growths, but also diseases which are usually not described in textbooks on tuberculosis. Thus, for example, an entire chapter is consecrated to each of the following diseases: Hydro- and Pyo-pneumothorax; Hemothorax in civil life as well as hemothorax following wounds of the chest; Chylothorax (pleuritic effusion, non-purulent, resembling milk in appearance); Bronchitis, narrowing and dilatation of the bronchi; Foreign bodies in the air passages; Asthma; Pulmonary vesicular emphysema; the various types of pneumonia covering four chapters. Edema, abscesses, gangrene and hydrated diseases of the lungs receive careful consideration; so does syphilis, actinomycosis, sporotrichosis, and aspergillosis.

Twenty-six chapters, covering 318 pages, are devoted to tuberculosis in all its phases, including etiology, pathology, symptomatology, complications, sanatorium treatment, specific treatment, artificial pneumothorax. In the chapter on etiology the reviewer found a statement of peculiar interest to tuberculosis workers in the United States. The mortality of grinders in England from all causes is not less than 30.9 per 1000 living, of pulmonary tuberculosis 15.0 and of other respiratory diseases 5.6. A similar though not quite so bad a condition in our own country prompted the National Tuberculosis Association to appoint a committee last year to study this problem with a view to diminishing the fearful death rate. A very satisfactory report was made at this year's meeting of the National Tuberculosis Association with suggestions for improvement by Dr. D. C. Jarvis of Barre, Vt., under the title, "A Clinical Study of Granite Dust Inhalation."

Because of our present situation regarding alcohol as contrasted with that in England, the following statement is not without interest. Here is what the distinguished authors have to say: "Alcohol is believed by many to be a potent factor in the etiology of the disease, and French statistics are quoted as showing a parallelism between the death rate from tuberculosis and the amount of alcohol consumed. In England, according to our experience, the majority of phthisical patients show no evidence or history of alcoholism, and for ourselves we doubt whether alcohol is *per se* a favoring agent to tubercle. There can be no question that, if taken in such excess as to produce the disease of chronic alcoholism—cirrhosis, alcoholic bronchitis, pharyngitis, or peripheral neuritis—it does beget a tendency to the acquisition of tubercle; even then, however, the disease is apt to run a chronic course."

It is regrettable that under treatment only sanatorium and climatic treatments are considered. The home treatment which had its origin in the excellent result obtained at Brompton, England, has not received any consideration at all, which, in view of the fact that the sanatorium is not available to all tuberculous patients, is an unfortunate omission in an otherwise so complete and excellent work. Printing, illustrations and binding are excellent, and the book can be recommended as one of the best textbooks on tuberculosis now in existence.

Treatise on Fractures in General, Industrial and Military Practice. By John B. Roberts, A.M., M.D., F.A.C.S., Emeritus Professor of Surgery in the University of Pennsylvania Graduate School of Medicine; President of the American Surgical Association; Membre de la Société Internationale de Chirurgie, and James A. Kelly, A.M., M.D., Associate Professor of Surgery in University of Pennsylvania Graduate School of Medicine; Attending Surgeon to St. Joseph's, St. Mary's, St. Timothy's and Misericordia Hospitals. Second Edition, Revised and Entirely Reset. Price $9.00. Philadelphia and London: J. B. Lippincott Company.

The first edition of this very practical treatise was published five years ago, since which time war experience has brought us many lessons of great value, especially in the treatment of compound fractures by projectiles, and has led us to revise some of our previously most cherished views. The knowledge so gained has been utilized by the authors in bringing their book fully up to date. The illustrations, of which there are more than nine hundred, most of them naturally roentgenograms, are excellent. The preface contains twenty-six axioms regarding the treatment of fractures, which the young practitioner may advantageously learn by heart, for they may save him, in case of emergency, from much trouble by starting him aright. The book is a capital and reliable guide to the diagnosis and treatment of fractures.

Therapeutique Clinique. Par Dr. Alfred Martinet. In Two Volumes. Paris: Masson & Cie., 1921.

The first volume of this commendable treatise comprises two sections which deal respectively with Therapeutic Agents and Therapeutic Techniques. The author is assisted by eight collaborators. The section on Therapeutic Agents is grouped by systems—the drugs most in vogue for the circulatory, respiratory, renal, nervous and other systems. In this plan cardiac stimulants and drugs which act on the peripheral circulation are followed by diuretics, urinary antiseptics, expectorants, purgatives, antispasmodics, hypnotics, etc. Ranked with drugs are diet, physiotherapy and psychotherapy. Under Therapeutic Techniques we find the resources of minor surgery, also grouped by the organ-systems. The author considers cutaneous (subcutaneous), circulatory or vascular, respiratory, urinary, digestive, and nervous system techniques. Under the last named we find lumbar puncture and spinal analgesia, under the digestive system gastric lavage and colonic irrigation, etc.

The second volume comprises two sections, viz., Treatment of Symptoms and Treatment of Diseases. The pages are so numbered that the two volumes can be found together in one book of 1340 pages containing over 300 illustrations. The section on Treatment of Symptoms is arranged alphabetically, beginning with Adenopathies and ending with Vomissements. The section on Treatment of Diseases begins with the Circulatory System, proceeding to the Respiratory System, and in succession the Urinary and Gastro-enteric Systems, Diseases of Nutrition, the Nervous System, Infectious Diseases, and so on. Some duplication is hardly avoidable. Thus under Treatment of Symptoms we find Edema, both cardiac and renal, which naturally is found again under Circulatory and Renal Disorders. It is, however, easy to make use of cross-references.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Thirty-third Annual Meeting, Held in Swampscott, Mass., June 2, 3 and 4, 1921.

THE PRESIDENT, DR. JOHN HOWLAND OF BALTIMORE, IN THE CHAIR.

President's Address.—Prolonged Intolerance to Carbohydrates.—Dr. JOHN HOWLAND of Baltimore delivered this address, in which he stated that many children with a prolonged sugar intolerance had a tendency to diarrhea even when taking woman's milk. It was apparently the sugar and not the fat that was responsible as was suggested by the fact that a diet deficient in sugar was borne even though it contained a considerable proportion of fat. Another important condition was the prolonged carbohydrate intolerance that developed after severe diarrhea, especially after numerous attacks of diarrhea. The first indication in these cases was to reduce the sugar to its lowest limits in a food which furnished the other requirements for adequate nutrition. Nothing could compare with protein milk in this respect. A polysaccharid such as farina was not only well borne at times but might even have a marked constipating effect. Young infants usually would not tolerate this, though with older infants it might be strikingly successful. These forms of carbohydrate intolerance were confined almost entirely to the first two years. Another form of carbohydrate intolerance occurred in children of all ages. It was commonly known as chronic indigestion or as intestinal infantilism of Herter. It had been found that, of all the elements of food, carbohydrate was the one that must be vigorously excluded. The dietary treatment might be divided into three stages: (1) That with protein milk alone which could be said to be more likely than any other food to bring satisfactory results. The protein milk stage should be continued until the stools were firm, distention slight, gas not in excess, and appetite good. (2) In this stage the diet should consist of protein milk as a basis reinforced by almost pure protein foods, such as curd without whey, scraped meat, certain forms of cheese, egg white, and eventually whole egg. The duration of this stage was many months; it might be years. This was not an ideal diet but it was an adequate diet. (3) In this stage carbohydrates were added very gradually with most careful observation of the digestive capacity. Bread, cereal, and potato were the last articles that could be allowed. The treatment was time-consuming but these patients repaid well the time spent upon them.

Blood Studies in the New Born.—Drs. WILLIAM PALMER LUCAS, BRADFORD FRENCH DEARING, and HAL R. HOOBLER of San Francisco presented this paper, in which they attempted to bring together the morphology, chemistry, coagulation, and pigment metabolism into a combined study of the blood of the normal newborn infant. The blood was obtained from a few hours after birth to the fourteenth day. Most of the figures represented serial studies obtained on alternate days from the same baby. In this way 150 babies were studied. The hemoglobin was high at birth, the average being 117, and gradually decreased thereafter. The hemoglobin of the sinus blood tended to be higher than that of the peripheral blood. The red blood cells were high during the first week and then gradually decreased, corresponding closely with the hemoglobin estimations. The same leucocytosis was observed as had been noticed by various authors, though it was by no means constant. The leucocytosis during the first week was definitely due to the polymorphonuclears. This continued to be so until the seventh day during which day the polymorphonuclears gradually declined, reaching the same level as the lymphocytes. The lymphocytes during the same period gradually increased and were still increasing at the close of these observations on the twelfth day. There was slight increase in the transitional cells which towards the end of the period of observation decreased slightly. The same was true of the eosinophiles. These counts in the sinus blood again showed a slight increase over those of the peripheral blood. The platelet counts during the first eight days corresponded very nearly to those of Dr. Mary E. Morse, who found immediately after birth, a blood count which varied from 412,000 to 100,000. They did not find any counts, however as low as the latter figure, the lowest figure being 195,000 on the eighth day. Neither were the platelets reduced in cases in which the coagulation was prolonged, nor was there any difference in cases that were markedly jaundiced and those that were slightly or not at all jaundiced. The estimations on nonprotein nitrogen, urea and uric acid, creatinine, sugar, and carbon dioxide had been repeated. They were unable to find any values on the carbon-dioxide combining power made on the blood of the newborn. Except for the low estimations which were found for sugar during the first four or five days their findings corresponded well with those of Sedgwick and others. Their explanation for the low sugar finding was that the infants were breast fed and received no supplementary food except water. Graphic curves showed a very definite drop in the nonprotein nitrogen, urea, and creatinine during the first few days and a definite rise in the carbon dioxide curve. During this period there was a high body metabolism. Forty-seven calcium determinations on twelve infants, ranging in age from one to twelve days, showed that the average calcium content of the plasma was higher in the new born than in older children. There was a constancy of the plasma volume throughout the series, each determination varying less than 1 mg. per 100 c.c. from the general average. Apparently in man a drop in plasma did not occur during the first twelve days in life. In general the corpuscle values tended to decrease slightly during the first few days. On the other hand there was a tendency for the whole blood values to increase. With reference to the coagulation time, any method which used a puncture wound must of necessity have certain inherent errors. The method used in these estimations was to obtain blood from the longitudinal sinus with an all-glass Luer syringe carefully sterilized. During the first five days there was a definite prolongation of the coagulation time. This showed clearly that during these first few days there was a definite and fairly constant condition in the blood of the newborn which favored the socalled hemorrhagic conditions of the newborn. During the period of prolonged coagulation time the serum-bilirubin curve was also increased, but it did not seem to affect the coagulation time in cases of marked jaundice. The prothrombin factor was investigated and it was proved that when the coagulation time was prolonged the prothrombin element was definitely diminished; after the fourth day the prothrombin apparently reached normal levels, though it might be delayed several days longer. The blood of the newborn did not show any defect in retractibility of the clot and there was no fibrolysis. This was exactly the condition that existed in hemophilia. They felt confident, therefore, that the factor involved in the ordinary case of hemorrhage of the newborn was due to diminution in the prothrombin element which was mainly derived from platelets and the defect was essentially a qualitative one of the platelets. So far as they had been unable to show the presence of any urobilin in the stools of newborn infants during the first twelve days of life, nor had they been able to demonstrate urobilin in the stools of infants up to ten weeks of age, although in older children it was easy to demonstrate its presence. Ninety cases were examined for bilirubin by a method which the writers proposed; of these 72 showed a positive reaction. At present they did not feel in a position to discuss what became of the red blood cells but they felt that this method of testing bilirubin gave a much better means than we had hitherto possessed of attacking this problem.

Dr. ALFRED F. HESS of New York said that the most remarkable thing about this study was the prolonged coagulation time of the blood in these newborn infants. This would indicate that they had latent hemophilia. These figures made one wonder that we did not see hemorrhage in the newborn more often. As these were normal figures the question came up as to what the figures would be in hemorrhage of the newborn.

Dr. FRITZ B. TALBOT of Boston said the blood-sugar studies were interesting compared with the respiratory quotient. The blood sugar was lowest at birth and rose on the third day and this was consistent with the respiratory quotient which went down and then on the third day began to rise. It shows that whatever sugar came into the world with the infant was used up quickly. These were very low figures compared with those of Folin.

Dr. LUCAS said that as to the question Dr. Hess had raised, that of potential hemophilia, they had found a coagulation time up to forty-five minutes without any bleeding at all. It was the same question that had come up in reference to hemophilia, namely, why the hemophiliac did not bleed all the time when the coagulation time was prolonged all the time. As to the sugar curves, they thought these very low and repeated the observations with the same results.

Some Observations on the Socalled Inanition Temperature of the Newborn.—Drs. CLIFFORD G. GRULEE and B. E. BONAR of Chicago presented this paper, which consisted of a study of 183 newborn infants with regard to transitory fever. They stated that for years it had been recognized that in a certain percentage of infants there occurred in the first few days of life a rise in temperature. This fever had not been accounted for satisfactorily. It offered an example of a febrile condition apparently simple in nature and it was thought that a careful clinical study of this condition might throw some light on the immediate factors that caused rise in temperature. The cases were divided into groups, according to weight. For normal cases the average weight loss was 6.2 per cent.; for 46 cases with a temperature between 99.2° and 100° F., the weight loss was 6.2 per cent.; for 16 cases with a temperature between 100.2° and 102° F., the average weight loss was 11.2 per cent. While at first glance this appeared to be significant, still if one examined carefully the individual cases it was found that among the cases with normal temperature the loss of weight was as great as 17.3 per cent., which was higher than in any case with fever. Their studies forced them to the conclusion that the temperature rise was not regularly to be explained on the basis of dehydration. The increased permeability of the intestinal mucosa for egg albumin during this period of life, the confirmation of the observation of von Reuss in regard to the finding of indican in the newborn, and the fact that the intestinal canal within twenty-four hours after birth was invaded by bacteria as far as the pylorus, suggested that the temperature elevation at this time might be ascribed to the absorption of some protein products, bacterial or otherwise, from the intestine of the newborn. With the stimulation of digestion and the flow of gastric and intestinal juices produced by taking in of foods, the meconium, which before contained small quantities of fluid and therefore a humidity too low for the growth of bacteria, was invaded by bacteria. The meconium consisted almost entirely of protein material, the destruction of which would most readily account for the presence of indican in such a large proportion of urines from newborn infants. With the introduction of breast milk the putrefactive processes in the intestines were reduced and there was a fall in temperature.

Dr. ROLAND G. FREEMAN of New York said he was disappointed with the results. It had seemed that dehydration did cause fever and that this would explain socalled inanition fever.

Dr. GRULEE said he shared Dr. Freeman's disappointment. He had hoped to be able to find that the fever in these cases was due to desiccation, but could find no such evidence in this investigation.

A Clinical Report of Simple Methods in the Care of Premature Babies.—Dr. WALTER LESTER CARR of New York presented this contribution, based on observations made at the Manhattan Maternity Hospital and Dispensary and the Woman's Hospital. The incubator room at the Manhattan Maternity was 6½ feet by 7, with a ceiling 12 feet high, and a single door opening from the main nursery. The air intake was from the window by means of a flue 9 by 2 inches. The air was carried back of a radiator. The room temperature was kept at 80° F. The incubator consisted of an aluminum tray with a hood which left the baby's head exposed. Over the open end there was a curtain to protect the baby's head and body. In the top of the incubator there were three openings for electric lights, placed on elbows so as not to interfere with the clothing. One 15 Watt light would give the incubator a temperature of 76° F.; two a temperature of 88° F., and three a temperature of 96° F. in three-quarters of an hour. A thermometer was placed inside the incubator where it could be observed by the nurse. A moderate heat was better than a constant high temperature. At the time of birth premature babies were anointed with oil but not bathed. The eyes were treated and an umbilical dressing applied. Diapers of cheesecloth and cotton were used. The more premature a baby the more feeble was its digestion. Breast milk should be given if it could be obtained. It should be drawn from the mother or wet nurse, diluted with equal parts of 5 per cent. milk sugar solution and fed with a medicine dropper or a Breck feeder. Premature babies did not bear high fat and this might give trouble even with mothers' milk. If cows' milk had to be given it should be boiled and diluted as ordered. Water must be given freely. Feeding intervals should be about two hours apart and should not exceed one or two drams each time. Whenever possible, feeding should be done without removing the baby from the incubator. Cane sugar was given to babies who had a persistent low temperature and it apparently helped heat production. Whatever methods of feeding were used it was essential to realize that the caloric requirements were high. Gavage and hypodermoclysis were sometimes employed. The administration of fluid through the longitudinal sinus was not a safe means of combating loss of weight as the sinus was small and pliable; other methods were less dangerous in babies under four pounds. Thirty premature babies were observed at the Manhattan Maternity, which was less than half of 1 per cent. of the number of confinements. The average weight of the babies on leaving the hospital was 4 pounds and ¾ ounces. The routine was to keep the baby in the hospital until the weight approximated 4 pounds. The average time the incubator babies were kept in the hospital was 36.8 days. Premature babies were prone to be rachitic.

Dr. HENRY DWIGHT CHAPIN of New York said that in the care of premature babies two things were of importance, the temperature of the incubator and the food, and of these the food was the more important. In his experience with several hundred incubator babies he had never been able to raise one without breast milk. In the exhibitions of incubator babies given for pay they always gave the babies breast milk and placed less importance on the temperature.

Dr. ISAAC ABT of Chicago said he had in mind just what Dr. Chapin had said with this addition, that ordinarily the temperature of the incubators was too high. These babies did not need a temperature of 80 degrees; 75 or a little over was enough. If the incubator was overheated the baby did poorly.

Dr. L. E. LA FETRA of New York said that in his experience a temperature of about 76° F. was best. If the temperature was higher the air became too dry and this caused the baby's lips to crack and exposed the child to infection. Feeding was very important and breast milk was desirable, but where it could not be obtained a modified milk which had been peptonized might be used with success.

Dr. FRITZ B. TALBOT of Boston said that temperature was almost equally as important as food. It did not make so much difference what the room temperature was, the important point was whether the baby's temperature was normal. The basal metabolism figures were important. A premature baby fell into the class of cold-blooded animals. The temperature was dependent upon the rate of metabolism in these babies. When the temperature was subnormal the basal metabolism was subnormal. The babies with subnormal temperatures did not gain until the temperature became normal, and when they began to gain the metabolism went up.

Dr. FREDERICK H. BARTLETT of New York emphasized the method of feeding. Not only the temperature and the kind of food were of importance, but the way in which the baby was fed often made a difference whether it remained stationary or gained in weight. It might be necessary to use a Breck feeder or gavage.

This was worth while insisting upon. The introduction of fluid would also help to establish a gain in weight and to prevent exhaustion.

Dr. J. P. Crozer Griffith of Philadelphia described an asbestos incubator which they were using. The baby was on a mattress placed on an asbestos tray which was over the lights. This worked well in the absence of a warm room. These babies required considerable heat. As soon as the temperature went down the babies did badly. The same thing was true of babies with malnutrition.

Malnutrition in Children of the Well-to-do.—Drs. Charles Gilmore Kerley, Edward J. Lorenza, Jr., and Roger DuBose presented this communication, in which they described a type of case of malnutrition which was referred by the family physician or brought independently, because the child remained persistently an inferior individual from a physical standpoint. These cases fell into groups. First there were those in which there was a maladjustment of the different food elements. Usually butter, cream, and 4 per cent. milk fat had been crowded. From the caloric standpoint the children had been fed above their requirements. The essential foods—meats, cereals, vegetables, and fruits were taken indifferently. In the management of these children the fact must be recognized that there must be a healthy desire for food and this was created by the withdrawal of fats and sugars in large measure. Three meals were given daily at five hour intervals, and nothing but water was allowed between meals. A low fat and sugar diet was given and skimmed milk, 16 to 20 ounces, only was allowed. In a second group hyperacidity of the stomach juices caused defective food intake and malnutrition, largely through the production of a poor appetite. The chief symptom of hyperacidity was a lack of desire for food. In cases of long standing nausea and vomiting were prominent symptoms. The pain and discomfort were greatest before meals. These patients usually responded to dietetic treatment. Three meals suitable for the age were given and usually nothing between meals but water. Extremes as regards temperature of foods and drinks were avoided. Condiments, candy, pastry, and raw fruits were excluded. A powder consisting of bicarbonate of sodium, 2 grains; bismuth subnitrate, 2 gr., and magnesium carbonate was given fifteen minutes before meals. A daily evacuation of the bowels was arranged for. A third group of cases were those in which defective intestinal mechanics delayed stomach emptying. For a child to have a normal desire for food there must be an interdigestive period of one hour. Retention was often due to pylorospasm occasioned by an anomaly or lesion lower down in the intestinal tract. In this group they had demonstrated ptosis, angulation, dilatation, sacculation. It was quite obviously impossible to outline a plan of management that would apply to all cases. A fourth group, comparatively small, contained the greatest number of failures. These were the underweight over-active, anemic, physically retarded, precocious children that one saw only occasionally before the third year. For this type of children Dr. Kerley said he had borrowed from the stock farmer the term "poor individual," and he marked them 50, 60, or 70 per cent. individuals. In conversation with Professor Lafayette Mendel he had suggested that the deficiency might relate to defective vitamine intake or defective vitamine utilization. In 125 cases they had used dried brewers' yeast, but a careful analysis of the histories failed to show that there was any benefit from the administration of the yeast. What favorable results they had had followed a plan of rest cure and a curtailment of activities, with school attendance delayed a year or two. Endocrine therapy, with the exception of the use of thyroid in the cretin, had been unsatisfactory.

Dr. L. Emmett Holt of New York said it seemed absurd to discuss in a society like this the abuse of over-feeding children, and yet he was glad Dr. Kerley had brought it up, since they still saw it practised not only by the general practitioner, but by the pediatrist. We still had a great deal to learn as to the amount of food a child could utilize. When a child refused to eat the food set before him, it should be taken away and nothing given him until the next meal time.

Dr. Henry Dwight Chapin of New York called attention to the interesting point that Dr. Kerley was one of the first to report results as to the use of yeast. It was time something was said about it. The newspapers were advertising yeast and saying "A yeast cake a day will keep the doctor away." He believed that if this society said something on this subject it would have an effect on these advertisers and would do some good.

Dr. Langley Porter of San Francisco spoke of fatigue as a factor in these forms of malnutrition. If one put these children to bed and saw that they rested they often improved very promptly.

Some Results of Studies of Anaerobic Bacteria in the Infant Intestine.—Dr. Langley Porter of San Francisco presented this contribution in which he recalled that at the 1919 meeting he had reported work done in the attempt to relate certain chemical intoxicative manifestations met with during infancy and childhood due to variations in the flora of the intestine. During this work evidence was encountered which led to the conclusion that some attacks of flatulence with abdominal distention were brought about by a preponderance of *B. welchii* in the intestines of the patient. An effective therapeutic plan for dealing with this condition was worked out and reported at the 1920 meeting. During the work they came upon certain refractory cases which made it seem that an intensive study of the anerobes to be found in the gut might aid in dealing with future cases of a like nature. In this study of anaerobes they had availed themselves of the methods developed by Dr. Hilda Heller of the Bacteriological Department of the Hooper Foundation. The attempt was made to test the influence of age, of varied diets, of the concomitant aerobic flora, and of abnormal intestinal conditions on the presence of individual anaerobes or groups of anaerobes, and evidence was sought which might relate anaerobes in the gut of the infants to clinical pictures or digestive or metabolic disturbances. The work indicated that anaerobic flora of the infant's stools was relatively simple, probably made up of a few types, the most prominent being *B. welchii, B. bifermentans, B. sporogenes*, and a terminal end sporulating organism of the tetanus amorphous group. Seventeen normal stools were studied, and so far as anaerobes were concerned 13 stools were negative and four showed the presence of *B. bifermentans*. This organism made its appearance on the fourth or fifth day. The results indicated that probably the first anaerobe to develop in the infantile intestinal tract was *B. bifermentans*. An experiment was carried out to determine the effect of a change of food and supplemental feeding on the anaerobic flora. One group of infants was kept on breast milk, using three supplements: (1) sterile water, (2) Ringer's solution, (3) saccharine water. Another group was kept on modified cows' milk, also using the three supplements. The aerobic flora was also studied to observe any change in the general type of organism present. Since there were fewer anaerobes in the infant's stool, it was not possible to note any effect of different foods or supplements. There was a change noted in the aerobic flora which had been noticed before by Eschner, namely, that the stools of the babies fed on breast milk showed the typical acidulic *B. bifidus* flora, while those fed on modified milk showed a flora of a more complex nature, approximating a semi-putrefactive flora. The three supplements had no noticeable effect on the aerobic or anaerobic flora of either group of babies. There seemed to be no relation between the flora of the mother and that of the child. Probably the child was not infected by the mother. The symbiotic relationship of aerobe to anaerobe was one of interest. It might be that certain symbioses promoted the growth of anaerobes whose by-products were harmful. In this connection the work of McIntosh on the toxicity of his "unidentified VIII," closely allied or similar to *B. bifermentans* was most suggestive. The high toxicity of this organism and the ease with which it might be overlooked led one to wonder if further investigation along this line might not throw light upon some of the obscure diseases that heretofore had been classified as intestinal intoxication.

Pneumococcus Peritonitis in Infancy and Childhood.—Dr. Henry Heiman of New York presented an analysis of five cases of pneumococcus peritonitis seen

at Mount Sinai Hospital within the past eight months. Pneumococcus peritonitis was a rare disease. During five years 125 cases of genuine peritonitis were admitted to the children's wards of Mt. Sinai Hospital, and the pneumococcus was present in but 15. The disease was more prevalent under 15 years of age. The majority of writers had noted the high incidence of the disease among females. In this series 13 were females and 2 males. The appearance of the peritoneal cavity was pathognomic. There was a diffuse inflammatory process characterized by the deposit of a large quantity of fibrin on the viscera, often matting together loops of intestine. The free pus was of a greenish yellow color, odorless, and containing flakes of fibrin. In some of the cases the process tended to become localized, adhesions developed, and abscesses formed, usually in the umbilical region. In nine cases in this series the type of disease was determined. In five cases it was Type I; in but one case it was Type II; in no case was it Tye III; in three cases Type IV. In five out of eight cases blood cultures were positive for the pneumococcus. A high leucocytosis was characteristic in these cases. The course of the disease was divided into three phases: (1) Sudden onset with severe abdominal pain, rising temperature, rapid pulse and prostration. The pain was usually generalized; it was most marked in the right lower quadrant. The degree of abdominal rigidity was not as marked as in other forms of peritonitis. Signs of fluid were not often elicited. (2) In this stage the condition improved. (3) This phase was characterized by the presence of a circumscribed mass in the abdomen, usually in the umbilical or hypogastric region. The temperature rise became intermittent and the patient gradually lost strength from the toxemia. Death ensued from toxemia or recovery might follow spontaneous rupture through the abdominal wall following operation. He did not agree with Mechant that diffuse and localized forms of the disease represented two entities caused by different strains of the organism. From acute appendicitis the diagnosis was most difficult. An overwhelming toxemia giving rise to early prostration, anxious expression, gray color, and sunken eyes were diagnostic of pneumococcus infection. Abdominal aspiration was used in four of their recent cases and the diagnosis of pneumococcus peritonitis was made in all of them before operation. An ordinary hypodermic syringe was used with the finest calibered needle. The point of preference for puncture was one inch below and one inch to the left of the umbilicus which would penetrate an area over the small intestines only. They were able to secure sufficient pus for smear examinations and cultures in all cases. The prognosis depended upon the localization of the inflammatory process and the involvement of other organs. Whipple had reported good results following the injection of antipneumococcic serum. Dr. Heiman had employed it intensively in four cases without avail. In those cases which presented localized collections of pus, all writers agreed that surgical intervention should be employed. There was difference of opinion in regard to the correct procedure in the acute diffuse stage of the disease. They believed the best treatment was to give an abundance of fluid by hypodermoclysis and proctoclysis, and to keep the patient under the influence of opium during the acute onset of the diffuse process. If toxemia tended to lessen it was advisable to wait for abscess formation before opening the abdomen. If, however, under supportive treatment no signs of improvement appeared, it was best to resort to surgery.

Dr. OSCAR M. SCHLOSS of New York mentioned that in puzzling cases in which there were no symptoms pointing to peritoneal infection they had found that it was sometimes possible to get fluid with a capillary needle when by aspiration they could get none. The needle was so constructed that it could not pass beyond the trocar except for a very small distance.

Dr. L. EMMETT HOLT called attention to one type of pneumococcus peritonitis in which the peritonitis was a part of the general pneumonitis, in which one found a pericarditis and a peritonitis. Frequently it gave no symptoms and was found only at autopsy. The diagnosis was almost impossible. The test Dr. Schloss spoke of might be very useful. Dr. Gibson was unqualifiedly in favor of operation in pneumococcus peritonitis, and his statistics showed a large percentage of recoveries. Evidently there was a difference of opinion on this point, and also as to whether the peritonitis was first generalized and then became localized or whether it was first localized and then became generalized. There was a question whether these children should be subjected to operation; he did not think this question had been settled.

Dr. ISAAC ABT of Chicago stated that he had seen quite a number of these cases. They usually ran a short and malignant course and were difficult to diagnose from appendicitis or ordinary peritonitis. A peculiar condition might occur during the course of the disease. The disease started with a severe, stormy onset. After two or three days of high fever and great toxemia, the patient lapsed into a calm semicomatose condition which reminded one of the condition seen when the appendix had ruptured. This was the condition which the surgeons called a "deceptive calm." After this the patient went rapidly downward and died. It seemed to him that even if one made an aspiration there would be some difficulty in telling whether one was dealing with a general peritonitis or a ruptured appendix. It seemed to him that exploratory operation might be justified and then one would know definitely whether or not an appendectomy was justified.

Dr. CHARLES GILMORE KERLEY of New York said he had seen quite a number of cases of pneumococcus peritonitis, all of the fulminating type. In one instance the child developed a paralytic ileus and died.

Dr. J. P. CROZER GRIFFITH of Philadelphia called attention to the difficulty in the early diagnosis of telling whether one was dealing with a true abdominal pain or a pain referred from the pleura. A referred pain might lead to the mistaken diagnosis of peritonitis. It seemed to him that it was better to take a chance until one was certain that the trouble was in the abdomen rather than to operate when it was unnecessary. He had seen instances in which early operation was performed and the patient died.

The Elements of Diet in Infancy, with Special Reference to the Employment of the Czerny and Kleinschmidt Butter-Flour Mixture.—Dr. J. P. CROZER GRIFFITH of Philadelphia said that it had long been thought that the giving of high protein percentages to normal infants was not a matter of indifference, and that the use of such food even in many cases of digestive disturbance might be harmful rather than beneficial. There was also the question whether the substitution for fat of large percentages of carbohydrates, useful as it might be in many cases, was one which was to be persisted in with entire satisfaction after health had been regained. Their conviction had long been that a relationship in the diet closer in some respects to the proportion seen in human milk was eminently desirable. Czerny and Kleinschmidt had devised a food which permitted the employment of a high fat percentage in combination with a percentage of carbohydrates also high, but with the protein reduced to approximately that of human milk. They insisted upon the great importance of having the ratio of carbohydrate and fat a fixed one. As soon as this relationship was altered, their results were not so good. They believed their good results were to be ascribed in part to the driving off of the volatile fatty acids from the milk fat, in part to the admixture of an amount of flour equalling that of the fat, in part to the chemical alteration of the flour produced by the browning which occurred during the preparation, and in part to the low protein percentage, the last being particularly important in weakly young infants. The proportions recommended were 20 grams of butter, 20 grams of flour, 15 grams of sugar, and 300 grams of water, but the relationship of butter to flour must remain the same. In preparation 20 grams of butter were placed on a pan and heated over a gentle fire until foaming took place and until the odor of the volatile fatty acids had disappeared. This required five to eight minutes; 20 grams of wheat flour were then added, the whole was boiled, rubbed through a sieve, and then mixed with the desired amount of previously boiled and cooled milk. For children under 3,000 grams in weight, one-third milk was added to two-thirds butter-flour mixture. For those 3,000 grams or over two-fifths of milk and three-fifths of butter

flour mixture were used. Not more than 200 grams per kilo body weight (about three fluid ounces per pound) should be given daily, and usually smaller amounts than this owing to the high caloric value of the food. Children fed in this way resembled healthy breast fed children. The improvement in general appearance and condition was striking, particularly in the development of fat in the lower part of the body. Results were particularly fine in weakly and premature infants, weighing less than 3,000 grams.

Personal Experience in Feeding Infants the Czerny-Kleinschmidt Butter-Flour Mixture.—Dr. A. GRAEME MITCHELL of Philadelphia read this paper in which he reported his experience with the butter-flour mixture in 32 infants. Emphasis was laid upon the necessity of following closely this method. For convenience they had estimated the amounts in tablespoonfuls. Thus it was sufficiently accurate to use 2 level tablespoonfuls of melted butter, 2½ tablespoonfuls of flour, 1½ tablespoonfuls of sugar, to 10 ounces of water. In whatever way the mixture was modified the amounts of butter and flour remained equal. In some cases the sugar should be decreased in amount or omitted entirely. It was quite easy to manipulate the percentages of fat, carbohydrates, and protein in this food as indications arose. Based upon the analysis of Dr. Leon Jones of the Pepper Medical Laboratory of the University of Pennsylvania, one fluid ounce of stock solution might be said to represent 26.6 calories. The mixture containing two-thirds of the stock solution and one-third milk might be said to represent fat 4.6 per cent., carbohydrates 8.2 per cent., protein 1.5 per cent., with a caloric value of 24.6 to the fluid ounce. Dr. Jones found that the fat of the stock solution after cooking consisted entirely of neutral fat and that no trace of fatty acids were to be found. This mixture, like other foods, had its indications and counterindications, and success in feeding depended upon the proper selection of cases. The food should be used cautiously if at all to infants suffering from infantile atrophy. They had found that it was the infant whose low body weight was due to failure to properly metabolize sufficient cow's milk fat who responded most favorably to the Czerny-Kleinschmidt mixture. In spite of high fat contents, vomiting seldom occurred. The removal of a baby from the butter-flour mixture was not a procedure to be accomplished quickly. Of the 32 infants fed on butter-flour mixture, 23 responded favorably by gain in weight and improvement in general condition. The two great lessons the study taught were: (1) That when fed with butter-flour infants might tolerate fat in a manner which could be accomplished probably by no other means as yet known to us. (2) That the truly remarkable results which often followed were a strong proof of the great need which the infant's anatomy possessed for a food containing a sufficiently large amount of fat.

Dr. CHARLES GILMORE KERLEY of New York said this was quite an involved proposition to put into the average family, and he did not see the necessity of following so many new and strange gods. Rotch had established the percentage method of feeding, and if one was having trouble with a difficult feeding case, he could write a prescription with the exact amounts of the various food elements. It seemed to him we were striving unnecessarily for new procedures. Too many proprietary preparations were being used by men too lazy to study up the suitable formula for the child. It would be well to recall some of the things taught some years ago and forgotten.

Dr. OSCAR M. SCHLOSS of New York stated that they had used the butter-flour mixture and had had the identical experience reported by Drs. Griffith and Mitchell. He thought that many babies did better on this mixture than when fed according to routine methods.

Dr. HENRY DWIGHT CHAPIN of New York said there might be danger in gettings things too simple. It might be possible to cut off the fats too much. A few years ago they were feeding all fats; now it was low fats or no fats. He thought the reason for this was the custom of estimating the caloric food requirements. It should be remembered that the different food elements were not interchangeable and particularly in early life. These papers were valuable because they showed how, in a certain class of cases, to keep the fats high.

Dr. L. EMMETT HOLT of New York expressed the opinion that the protein content of the butter-flour mixture was too low for a long continued diet. The formulas of Rotch were based on the 3-6-1 ratio and after physicians used this ratio for a time they found that it was unsuccessful. They came to believe it was because of the high fat content, but he thought that it was the low protein rather than the high fat that accounted for the failure.

Dr. ALFRED F. HESS of New York stated that the diets upon which the babies in the Hebrew Infant Asylum did best were the Schlüss milk, made of 160 c.c. of cream and 160 of milk to the liter, to which was added a certain amount of flour and sugar. It was similar to this mixture except that the fatty acids were not driven off. On that diet the children not only thrived but the texture of the skin and muscles was better than in the average bottle fed baby. This seemed to occur in spite of the fact that it contained fatty acids.

Dr. J. CLAXTON GITTINGS of Philadelphia stated that he had had babies gain in weight with this method of feeding. He emphasized the fact that the composition of the butter-flour stock did not represent the final percentage of protein, but only that before the milk was added.

Dr. GRIFFITH of Philadelphia said that twenty-five physicians had used the butter-flour feeding and admitted that the results were surprisingly good. This was not meant for temporary feeding, but was a permanent food.

Dr. MITCHELL, in closing the discussion, asserted that the butter-flour method of feeding was a percentage method. It was an easy and simple method of feeding but not a lazy one. It was simply a way to get an infant to take more fat. It was a method that helped infants that did not get along well on cow's milk mixures, and it might be true that it could be used indefinitely.

The Use of Thick Cereal Mixtures in Difficult Feeding Cases.—Dr. HENRY DWIGHT CHAPIN of New York read this paper. (See page 539.)

Dr. CHARLES HENDEE SMITH of New York stated that the babies at Bellevue were put on thick cereal gruels by the interns' orders, and many children retained these gruels when they could keep nothing else down. They had a formula for which he thought Dr. La Fetra was responsible, which called for one tablespoonful of farina to five or six ounces of milk and water. It was practically the same as the formula Dr. Chapin had given.

Dr. HENRY HEIMAN of New York said he thought they ought to welcome any new mixture that would feed ten to fifteen per cent. of difficult feeding cases. All babies, however, could not take these foods. He thought they all recognized that they had to adapt the food to the baby and not the baby to the food. It was their duty to try all these methods, and thick cereal mixtures were useful in some cases.

Dr. J. P. CROZER GRIFFITH stated that some babies did surprisingly well on these thick cereal mixtures. They had a very capable nurse who succeeded in getting the babies to take these mixtures by taking the rubber one-half of a hygiea bottle and with a spoon pushing the cereal through so that the baby sucked it.

Dr. ROWLAND G. FREEMANN of New York said these thick cereal mixtures were most successful for vomiting babies. He had used them with great success and thought it strange that more physicians did not prescribe them. When they saw babies growing atrophic they used these thick cereal mixtures. They had used a mixture as strong as a teacup of cereal to ten ounces of milk and water.

Dr. CHARLES GILMORE KERLEY of New York stated that he had used thick cereal feeding in 14 cases of persistent neuropathic vomiting with very decided success. It had been a means of inestimable value in the type of children mentioned. He had used Dr. Mixsell's mixture consisting of farina, cane sugar and dextromaltose.

Dr. LANGLEY PORTER of San Francisco said he had been using thick cereal feeding for a number of years, and had been impressed with the fine condition of the children fed in this way; they were solid and hard like well-fed breast babies. He supposed the good result

was due to the fact that these flours were high in salts and the mineral balance was well maintained. Some babies on farina became constipated and a few had diarrhea. In some babies they had found that rice flour cooked in the same way would enable one to continue thick feeding and to overcome diarrhea. On the other hand it had been brought out at St. Paul that rye flour was a laxative and by using it constipation might be overcome and the thick cereal feeding continued. They used a double boiler and cooked the cereal two hours. They used one tablespoonful of farina to 5 of liquid, 1 of rice to 7, and 1 of rye flour to 6, to get good results. They had been much impressed with the value of thick cereal feeding in all cases in which high saccharolytic bacteria were found and where the stools were frothy and acid.

Dr. ISAAC ABT of Chicago said he was not opposed to thick cereal feeding, but he wished to call attention to one danger, and that was that by feeding a high starch percentage one might produce indigestion. One should watch the percentage of starch and see that it was not too high. If one made the mixture with skimmed milk this danger might be produced easily. He thought it should be emphasized that the protein side must not be disregarded.

Dr. KENNETH BLACKFAN of Cincinnati emphasized the desirability of giving water with thick cereals and starchy foods. He said they had used these starchy foods for a long time. Dr. McClure had used them in infants with pyloric stenosis and malnutrition who were not doing well on whole milk.

Dr. CHAPIN, in closing the discussion, said that these feedings were only for temporary use. They were for those cases that had lost weight and in which the loss could not be stopped by ordinary means. All these babies were tried on normal formulas before thick cereal feeding was resorted to. He had found that the degree of thickness given by these formulas was better than that of the thicker mixtures. His nurse had improved upon the method adopted by Dr. Griffith's nurse. She pushed the cereal from the spoon into the baby's mouth with a tongue depressor. This was simply another method of feeding atrophic babies for a time until one could get them on a more rational formula.

Critical Consideration of the Four-Hour Nursing and Feeding Interval.—Dr. THOMAS S. SOUTHWORTH of New York read this paper, in which he stated that the four-hour interval had been advocated by Czerny and had been widely adopted in the expectation that it would clear away many of the difficulties of the nursery. Within limits it had proved helpful, but like many other dicta from "Mittel Europa" it was too sweeping for universal application. The four-hour interval seemed to be admirably adapted for the vigorous normal infant at full term, nursing a normal mother with an abundant supply of good breast milk. However, this group throve in former days with regular three-hour intervals or two-hour intervals, or indeed in unregulated cases in which the infant asserted its own times and requirements. There were certain types of more exceptional cases in which the longer interval proved distinctly superior. Two of these stood out in their appeal to the obstetrician. One was when there was tenderness of the mother's nipples with the risk of infection and mammary abscess, and the second type was that in which there was over-rich fat breast milk. Mothers also found the longer interval to their liking as giving them more freedom, and they naturally favored it and advertised it. Many obstetricians were the first to adopt it, and when the case reached the general practitioner, he continued the custom. However, the longer interval found useful in meeting or avoiding certain conditions of maladaptation, when adopted too enthusiastically as routine, worked injury to other more important types of maladaptation.

Premature infants required more frequent feeding than those at term. Of the full-term infants there was the sluggish dormant infant with difficulty stimulated to take a sufficient supply of breast milk in five nursings; there was the baby who was too weak or learned with difficulty to take the nipple, especially from moderately malformed breasts and did not empty the breast; the nervous and inexperienced mother who did not know how to cooperate with the baby and defeated its efforts; there was finally the large and perhaps increasing number of mothers whose breast milk, while scanty and insufficient, was capable of being made abundant enough to establish maternal nursing wholly or in part if stimulation was maintained with adequate frequency. For these above cases the four-hour interval was irrational and injurious.

Complemental feedings given at the conclusion of nursing, to make up deficiency in breast milk, were always justifiable when occasion demanded and should be employed more frequently, but the substitution ignorantly made of one or more bottle feedings to take the place of already too infrequent breast nursings was the most scientific way of drying up the breast milk and precipitating unnecessary weaning. In many instances complemental feeding, coupled with a return to shorter intervals, produced the best results. Because a four-hour interval was applicable to breast feeding it did not necessarily follow that it was applicable to bottle feeding. It was a question in the writer's mind whether in the young infants who must necessarily be brought up on the bottle, the total results were any better by adopting too rigidly the longer interval.

The Effect of Compressed Yeast in the Food of Infants.—Dr. MAYNARD LADD of Boston stated that the food for an infant must have the three known vitamines—fat soluble A, water soluble B, and C anti-scorbutic, which must be present in sufficient amounts. It was no less important to have sufficient amounts of fats, carbohydrates, and protein, mineral matter, and water to meet the individual requirements of the child. Experimental feeding had been carried out in lower animals to determine the part that was played by these three vitamines in nutrition, but conclusions reached in the feeding of rats, guinea pigs, fowls, dogs and pigs might be applied too directly to infants. Osborne and Mendel, for example, had shown clearly that their experimental animals (rats) failed to show normal growth when milk was added to their diet, whereas, with a small amount of yeast normal growth followed. Ten cases were reported in which the object had been to determine whether the addition of such an accessory as yeast, which presumably was rich in water soluble B vitamine, would favorably influence the development of infants in the first year, the other factors being managed along lines of rational feeding. The cases in this series were all difficult feeders and were carefully observed for varying periods. The weight charts gave evidence of satisfactory development, but careful analysis of the rate of weight development during the periods with yeast and without yeast did not show any benefit that could be attributed to the yeast itself separate from other factors entering into the feeding problem. As to the value of yeast in furunculosis, the series of cases gave no definite evidence. One child developed furunculosis while taking the yeast. The only ill effects were in one baby who developed a severe fermentative diarrhea soon after the yeast was begun, but later, when this was corrected, it took another dose of yeast with no bad effects, but still without benefit to its nutrition.

The Protein Requirements of Children.—Dr. L. EMMETT HOLT read this paper. He stated that the total protein required was to a large extent dependent upon the character of the protein given. Proteins differed greatly in their amino-acid content. Vegetable proteins were lacking in amino-acids essential for growth, while animal proteins were much richer in these substances and corresponded more closely in composition to the proteins of the body. In adults, protein was required only for maintenance and repair; in children, in addition, protein must be supplied for growth. While vegetable proteins might be sufficient for maintenance, the animal proteins were needed for growth. The protein furnished to the nursing infant was only from 8 to 12 grams daily up to nine months of life; this was equivalent to only about 1½ grams per kilo. This small amount was sufficient for growth and maintenance during the most active period of growth. The reason for this was to be found in the very high grade of the protein of woman's milk which was especially rich in essential amino-acids. When cow's milk was the food a much larger amount of protein was required

as the protein of cow's milk was deficient in some of the important amino-acids, especially cystin. It was therefore necessary to give two or three times as much protein as was contained in woman's milk. Low protein or an insufficient amount of protein was one of the reasons for the failure of condensed milk as a food and also for the want of success which attended the use of such milk formulas as those which were based on the percentage composition of woman's milk. No experimental work had been done, nor in fact was it possible, to determine the exact protein requirement of growing children. It seemed wise in view of the great need of protein for growth to allow a liberal amount to growing children especially since no harm had ever been shown to result from protein given in these amounts. Tables were presented showing the amount of protein taken by one hundred healthy children in their usual diets. These averaged about 40 grams daily at one year; 60 grams, at six years; 80 grams, at twelve years; 115 grams, at sixteen years. About two-thirds of the protein taken was of animal origin and one-third was vegetable protein.

(*To be continued.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF MARYLAND.

December 14-17, 1900.

(*Continued from page* 483.)

CHEMISTRY.

1. What are fats chemically? What changes do they undergo during digestion?
2. What is the significance of Bence-Jones protein in the urine, and how is it detected?
3. Give a brief discussion of acidosis.
4. What is glycogen chemically, and where is it found in the body?
5. Give test for indican in the urine.
6. How is uric acid formed in the body?
7. Tell of the general color reactions of proteins and give the technic of any one of them.
8. What substances may be found in excess in the blood in a severe case of nephritis?
9. Give tests for acetone and diacetic acid in the urine.
10. What changes take place in the sugar content of the blood and urine in diabetes? How do you estimate the sugar in the blood.

MATERIA MEDICA.

1. Arsenic—In what class of drugs does it belong? How found? The preparations and doses, using official terms.
2. Name the preparations and doses of ammonium.
3. Sodium—Name six preparations of sodium and give doses.
4. Nux vomica—Describe it, give preparations and doses. Name the two alkaloids and give doses.
5. Opium—(*a*) Where and how obtained? (*b*) Give six preparations and doses. (*c*) What is the chief alkaloid of opium.
6. Iron—(*a*) Give six official preparations and doses. (*b*) What are the incompatibles?
7. Write a prescription—48 pills for adult—(*a*) containing iron, quinine, strychnine, and arsenic. (*b*) One containing three diuretics, using official terms.
8. What are carminatives? Name some of the most important and tell how administered.
9. Name and describe methods of introducing medicines into the system.
10. State what you know of the use and effect of thyroid extract. Give the official term.

THERAPEUTICS.

1. Write a prescription in Latin, without abbreviations, containing four ingredients, stating use.
2. Write another prescription in Latin, without abbreviations, containing four ingredients, and state the therapy or expected action of each.
3. Give classification of food stuffs and state their special uses.
4. In the preparation of a dietary to meet caloric needs what feature should receive careful consideration?
5. What is the accepted percentage of protein of the total metabolism, and what follows deprivation of protein?
6. From the standpoint of the circulation what is the main effect of a venesection? How are the favorable results of a venesection manifested?
7. Give the conditions in which the succinate of sodium often appears to be of decided value.
8. State the physiological action of and therapy of pilocarpus. In what prevalent winter ailment is it serviceable?
9. State the physiological action, therapy, and danger of hyoscine.
10. Give the therapy of senna and name common preparations.

ANSWERS.

CHEMISTRY.

1. Chemically, *fats* are glyceric esters, or compounds of fatty acids with glycerin.

Digestion of fats. In the stomach, the gastric juice dissolves the connective tissue binding the fat cells together, and sets free the fat, which passes into the duodenum. Here the steapsin of the pancreatic juice (aided by the secretions) splits up the fats into glycerin and fatty acids.

Thus:

$$C_3\,H_5\,(O.\,C_{15}\,H_{31}\,CO)_3 + 3H_2O = C_3\,H_5\,(OH)_3 + 3\,C_{15}\,H_{31}\,COOH.$$

2. *Bence-Jones protein* is a primary proteose; it is believed to be pathognomonic of multiple myeloma.

To detect it: Acidify the urine with acetic acid, and heat gently; if Bence-Jones protein is present a precipitate forms at about 60° C., which dissolves (partially or entirely) as the boiling point is reached, and reappears on cooling.

3. *Acidosis* is a condition in which the blood and tissues of the body are relatively increased in acidity and decreased in alkalinity. The blood is never acid in reaction. The condition is found when there is a disturbance in the metabolism of the fats combined with insufficient carbohydrate metabolism. It is noted in starvation, in fevers, and in diabetes. Ordinarily, in health, the fats are gradually oxidized to simpler fatty acids, and are finally split up into carbon dioxide and water. In the condition of acidosis, the belief is that the fats are split up into simpler fatty acids as far down in the series as butyric acid, and that then oxybutyric acid, diacetic acid, and acetone are produced; these substances are called the acetone bodies and may be found in the urine when acidosis is present. At the same time, the amount of ammonia in the urine is increased, and the alveolar carbon dioxide is diminished.

4. Chemically, *glycogen* is a polysaccharide carbohydrate. *It is found in the body* in the liver, placenta, white blood corpuscles, cartilage cells, muscle tissue.

5. *Test for indican in the urine.*—The urine is mixed with one-fifth of its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride; a few drops of chloroform are added, and the mixture strongly shaken 1 to 2 minutes. With normal urine the chloroform remains colorless or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.—(From Witthaus' *Essentials of Chemistry.*)

6. *Formation of uric acid in the body.*—"Uric acid was long regarded as a product of general proteid metabolism and for chemic reasons an antecedent of urea. This view has been abandoned. At present it is believed that it is a cleavage product of nuclein, a constituent of all cell nuclei. In the metabolism of nuclein a proteid and nucleic acid are formed, from the latter of which uric acid is derived. Nucleic acid when decomposed yields a series of bases, such as xanthin, hypoxanthin, adenin, guanin, etc. Because of the fact that these bodies can also be obtained from a synthetized body termed *purin* they are known collectively as the purin bases. Though there is a close relationship between uric acid and the purin bases, it has been impos-

sible to experimentally derive one from the other. When hypoxanthin, however, is given internally it is oxidized and converted into uric acid. It is extremely probable, therefore, that uric acid is an oxidation product of one or more of the purin bases. It is probable, however, that not all of the uric acid eliminated is derived from the nuclein of tissue cells and their decomposition products, the purin bases. Some of it is undoubtedly derived from the nucleins contained in foods. The uric acid eliminated is therefore partly endogenous and partly exogenous in origin." (Brubaker's *Text Book of Physiology.*)

7. *The chief color reactions of the proteins* are: (1) The *xanthoproteic reaction;* if a few drops of nitric acid are added to a solution of a protein such as white of egg, the result is a white precipitate; this and the surrounding liquid become yellow on boiling and are turned orange by ammonia. (2) *Millon's reaction.* Millon's reagent is a mixture of mercuric and mercurous nitrate with excess of nitric acid. This gives a white precipitate which is turned brick-red on boiling. This reaction depends on the presence of the tyrosine radical. (3) *Copper sulphate (Rose's or Piotrowski's) test.* A trace of copper sulphate and excess of strong caustic potash give with most proteins a violet solution. Proteoses and peptones, however, give a rose-red color instead; this same color is given by the substance called *biuret;* hence the test is generally called the *biuret reaction.* This name does not imply that biuret is present in protein; but both protein and biuret give the reaction because they possess a common radical, namely, two $CONH_2$ groups linked to a carbon or nitrogen atom, or to one another. The native proteins give a violet color, because the red tint of the copper compound with the biuret group is mixed with another copper compound with a blue color. (4) *Adamkiewicz reaction.* When a solution of protein is mixed with a dilute solution of formaldehyde, and then excess of commercial sulphuric acid is added, an intense violet color is obtained. This is due to the tryptophane radical. (From Halliburton's *Handbook of Physiology.*)

8. *In a severe case of nephritis, the following substances may be found in excess in the blood:* Urea nitrogen, uric acid, creatinin, and (sometimes) the acetone bodies, beta-oxybutyric acid, diacetic acid, and acetone.

9. *Test for acetone in the urine.*—Add a few drops of a freshly prepared solution of sodium nitroprusside and then KOH solution, to the suspected urine; if acetone is present, the liquid becomes of a ruby-red color which changes to purple in excess of acetic acid.

Diacetc acid is detected by slowly adding a solution of ferric chloride to the urine, when a Bordeaux-red color appears; this color disappears on boiling.

10. In diabetes, the sugar content of the blood and urine is high.
